Received January 27, 2010

Introduction

Molecular recognition in biological systems relies on the existence of specific attractive interactions between two partner molecules. Structure-based drug design seeks to identify and optimize such interactions between ligands and their host molecules, typically proteins, given their three-dimensional structures. This optimization process requires knowledge about interaction geometries and approximate affinity contributions of attractive interactions that can be gleaned from crystal structure and associated affinity data.

Here we compile and review the literature on molecular interactions as it pertains to medicinal chemistry through a combination of careful statistical analysis of the large body of publicly available X-ray structure data and experimental and theoretical studies of specific model systems. We attempt to extract key messages of practical value and complement references with our own searches of the CSD^{a,1} and PDB databases.² The focus is on direct contacts between ligand and protein functional groups, and we restrict ourselves to those interactions that are most frequent in medicinal chemistry applications. Examples from supramolecular chemistry and quantum mechanical or molecular mechanics calculations are cited where they illustrate a specific point. The application of automated design processes is not covered nor is design of physicochemical properties of molecules such as permeability or solubility.

Throughout this article, we wish to raise the readers' awareness that formulating rules for molecular interactions is only possible within certain boundaries. The combination of 3D structure analysis with binding free energies does not yield a complete understanding of the energetic contributions of individual interactions. The reasons for this are widely known but not always fully appreciated. While it would be desirable to associate observed interactions with energy terms, we have to accept that molecular interactions behave in a highly nonadditive fashion.^{3,4} The same interaction may be worth different amounts of free energy in different contexts, and it is very hard to find an objective frame of reference for an interaction, since any change of a molecular structure will

have multiple effects. One can easily fall victim to confirmation bias, focusing on what one has observed before and building causal relationships on too few observations. In reality, the multiplicity of interactions present in a single protein–ligand complex is a compromise of attractive and repulsive interactions that is almost impossible to deconvolute. By focusing on observed interactions, one neglects a large part of the thermodynamic cycle represented by a binding free energy: solvation processes, long-range interactions, conformational changes. Also, crystal structure coordinates give misleadingly static views of interactions. In reality a macromolecular complex is not characterized by a single structure but by an ensemble of structures. Changes in the degrees of freedom of both partners during the binding event have a large impact on binding free energy.

The text is organized in the following way. The first section treats general aspects of molecular design: enthalpic and entropic components of binding free energy, flexibility, solvation, and the treatment of individual water molecules, as well as repulsive interactions. The second half of the article is devoted to specific types of interactions, beginning with hydrogen bonds, moving on to weaker polar interactions, and ending with lipophilic interactions between aliphatic and aromatic systems. We show many examples of structure–activity relationships; these are meant as helpful illustrations but individually can never confirm a rule.

General Design Aspects

Entropic and Enthalpic Components of Binding. Like any other spontaneous process, a noncovalent binding event takes place only when it is associated with a negative binding free energy (ΔG), which is the well-known sum of an enthalpic term (ΔH) and an entropic term ($-T\Delta S$). These terms may be of equal or opposite sign and thus lead to various thermodynamic signatures of a binding event, ranging from exothermic to entropy-driven. An increasing body of data from isothermal titration calorimetry (ITC) is available on the thermodynamic profiles for many complexes.^{5,6} Where crystal structure information exists as well, it is tempting to speculate about the link between thermodynamics and geometry of protein–ligand complexes. A rough correlation between the burial of apolar surface area and free energy could be derived,⁵ but beyond that, practically useful relationships between structure and the components of free energy have remained elusive. This is not surprising, as both entropy and enthalpy terms obtained from calorimetric experiments contain solute and solvent contributions and thus cannot be interpreted on the basis of structural data

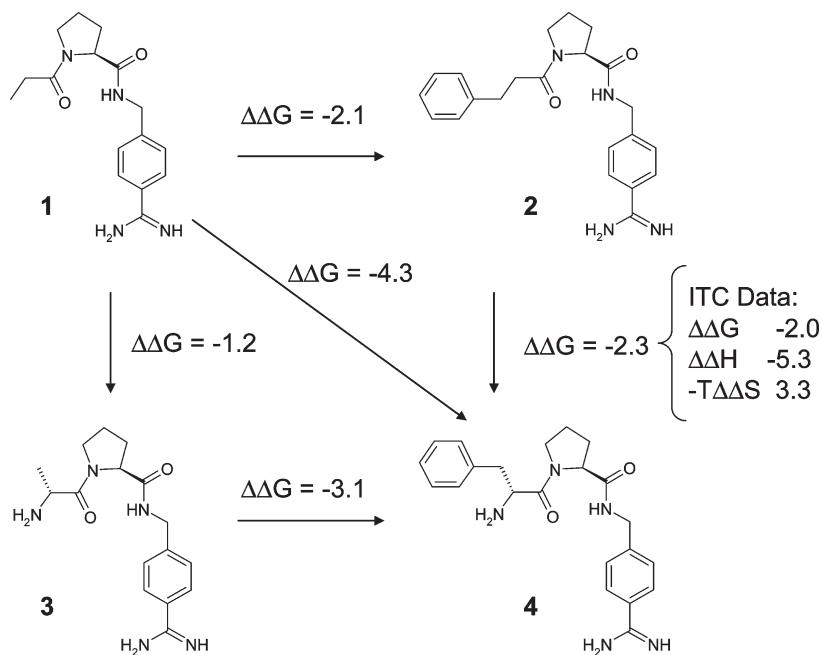

Figure 1. Cooperativity of hydrogen bond formation and hydrophobic contacts in a set of thrombin inhibitors. Extension of the lipophilic side chain alone increases affinity by 2.1 kcal/mol. Addition of the amino group increases affinity by 1.2 kcal/mol. Cooperativity therefore amounts to $4.3 - 2.1 - 1.2 = 1.0$ kcal/mol. Data from refs 30 and 31 were converted to kcal/mol and rounded to 1 decimal place.

alone. The direct experimental estimation of solvent effects has been attempted⁷ but always requires additional assumptions. Only theoretical treatments allow a separation of these effects.⁸ Thus, computer modeling can support the interpretation of experimental observations.

Furthermore, from an experimental point of view, such studies are very demanding: Error margins are significantly larger than the fitting errors usually reported⁹ and depend on subtle details of experimental setup.¹⁰ Entropy and enthalpy values are sensitive to conditions such as salt concentrations and choice of buffer. Protonation and deprotonation steps associated with the binding need to be understood in detail,¹¹ as significant differences in protonation states can occur even within congeneric series of ligands.¹²

Freire suggested that best-in-class drugs bind to their targets in an enthalpy-driven fashion.¹³ His group established a comprehensive ITC data set on HIV protease inhibitors, concluding that second- and third-generation inhibitors bind through a strong enthalpy component. One may argue that this could be caused by a higher number of specific backbone interactions, partially replacing the larger lipophilic surface area of the first generation inhibitors, and that the larger reliance on backbone interactions could be the cause for the broader coverage of HIV protease mutants. Still, even in this data set small structural changes cause large difference in relative ΔH and $T\Delta S$ contributions that are hard to explain structurally. Amprenavir and darunavir differ only in one cyclic ether moiety, but there is a drastic difference of about 10 kcal/mol in binding enthalpy between these two ligands.¹⁴

Since entropic and enthalpic components of binding are highly dependent on many system-specific properties, the practitioner has to conclude that optimizing for free energy is still the only viable approach to structure-based design. Perhaps the greatest advantage in the attempt to interpret components of ΔG is that it forces us to think about two fundamental topics in unprecedented detail: viewing

protein–ligand complexes as flexible entities rather than fixed structures and the role of desolvation effects. These two topics will be discussed next.

Flexibility and Cooperativity. A discussion of the thermodynamics of ligand binding is not complete without mentioning the phenomenon of entropy–enthalpy compensation. The validity and generality of this phenomenon have been a contentious topic for many years. There is ample evidence of meaningless and spurious correlations between ΔH and $T\Delta S$, often due to far larger variations (sometimes through larger experimental errors) in ΔH than in ΔG .^{15,16} Also, compensation is no thermodynamic requirement.^{17,18} If changes in ΔH were always compensated by opposing changes in $T\Delta S$, optimization of binding affinities would hardly be possible.

Nevertheless, there seems to be a mechanism behind the compensation frequently observed¹⁹ in host–guest chemistry²⁰ and in protein–ligand interactions.²¹ In short, the tighter and more directed an interaction, the less entropically favorable it is. Bonding opposes motion, and motion opposes bonding.²² However, the detailed nature of these compensatory mechanisms is highly system-dependent and the mechanisms do not obey a single functional form. As a consequence, noncovalent interactions can be *positively cooperative*; that is, the binding energy associated with their acting together is greater than the sum of the individual binding free energies. Detailed studies by Williams on glycopeptide antibiotics indicate that cooperativity may be caused by structural tightening upon introduction of additional interactions; interaction distances become shorter and enthalpically more favorable. Evidence for such effects also exists in protein–protein²³ and protein–ligand complexes. Streptavidin becomes better packed upon binding to biotin as evident from structural, mass spectrometry, and deuterium exchange NMR experiments.²⁴ Hunter has proposed an alternative model of cooperativity.²⁵ Flexible molecules may exist in a series of partially bound states, where not all

interactions are made at the same time. Upon introduction of further interactions, the balance shifts toward more frequent formation of the interactions and less mobility. There is experimental evidence for both the structural tightening model²⁶ and the model of partially bound states²⁷ in different systems. Since proteins bind ligands in many geometric arrangements ranging from loosely surface-bound to deeply buried, it is likely that both are valid in different contexts. Ligands with increasingly longer linear and lipophilic side chains have been observed to bind with increasingly favorable entropies and increasingly unfavorable enthalpies against trypsin²⁸ and carbonic anhydrase.²⁹ Longer side chains retain more residual mobility and form less tight (or less frequent) interactions with the protein surface, trading enthalpy for entropy.

In an impressively comprehensive study on several series of thrombin inhibitors, the Klebe group has analyzed the sources of cooperativity between a lipophilic interaction and a hydrogen bond.^{30,31} The findings from this study can be summarized as follows: (i) In the presence of the amino substituent forming a hydrogen bond to the backbone of Gly216, the gain in binding free energy of a given P3 substituent is significantly larger. This is illustrated by the double functional group replacement cycle in Figure 1. (ii) Both *B*-factor analyses and MD studies confirm a decrease in residual motion of the P3 substituent in the presence of the hydrogen bond. MD studies also indicate that the average hydrogen bond distance is shorter with a P3 substituent attached. (iii) In accordance with this finding, the introduction of the hydrogen bond makes bonding significantly more exothermic, but the gain in enthalpy is largely compensated by an entropic disadvantage.

What can we learn from this study? First, small changes in ΔG often mask large and mutually compensating changes in ΔH and $T\Delta S$. Focusing on ΔG in designing new molecules is certainly still the safest bet. Second, in medicinal chemistry we often rely on cooperative effects without even noticing, and yet in our minds we attempt to decompose binding free energies into additive elements. There is nothing wrong with this empirical approach as long as we keep in mind that it is primarily useful to teach us about the limits of additivity. The knowledge that specific interactions, in particular strongly directed ones like hydrogen bonds, rigidify a protein–ligand complex may help us to exploit cooperativity in a more rational fashion. The Klebe data should also make us think about the degree of mobility required in interactions with different parts of the protein. Flexible domains may require more flexible ligand moieties than highly ordered ones. The thermodynamic signature of a “good” ligand is not necessarily dominated by an enthalpic term. Our traditional focus on visible interactions and on the induced fit model has led to an overly enthalpic view of the world that neglects flexibility and cooperativity. It also neglects local solvation phenomena, whose details strongly affect the thermodynamic profile of a molecular recognition event. We should learn to incorporate these into our thinking, at least in a qualitative fashion.

Desolvation and the Hydrophobic Effect. The classic concept of the hydrophobic effect is as follows: A hydrophobic solute disrupts the structure of bulk water and decreases entropy because of stronger bonding and ordering of water molecules around the solute. Such disruptions can be minimized if nonpolar solute molecules aggregate. Water then forms one larger “cage” structure around the combined solutes, whose surface area will be smaller than the combined

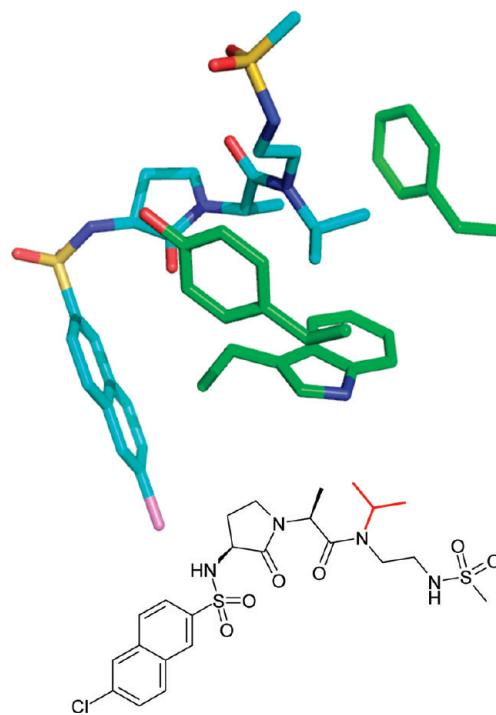

Figure 2. Binding mode of a factor Xa inhibitor from GSK.⁴⁰ The depicted compound (PDB code 2j4i) has a K_i of 1 nM. Replacing the isopropyl group (marked in red) by hydrogen reduces the affinity to 39 μ M.

surface areas of isolated solutes. This maximizes the amount of free water and thus the entropy.

If this mechanism were the sole driving force for a protein–ligand interaction, all binding events involving hydrophobic partners would be entropy-driven. But spectroscopic evidence indicates that hydrogen bonds at hydrophobic surfaces are weaker³² and water molecules more flexible³³ than originally assumed. In addition, already simple water models show that size and surface curvature of solutes have a dramatic impact on their solvation thermodynamics.³⁴ Complexation thermodynamics driven by enthalpic forces have been regularly observed in host–guest chemistry and have been dubbed the “nonclassical hydrophobic effect”.³⁵ Homans has carefully studied the ligand-binding thermodynamics of the mouse major urinary protein (MUP). The key to the extremely favorable enthalpy of binding of ligands to MUP seems to be the suboptimal hydration of the binding pocket in the unbound state.³⁶ The negative change in heat capacity upon binding, a hallmark of the hydrophobic effect, is also observed with MUP ligands. It is largely determined by ligand desolvation, with minor contribution from desolvation of the protein.³⁷ Similar observations have been made for hydrophobic cavities in other proteins.³⁸ It is quite likely that the synthetic hosts displaying an enthalpy-driven complexation behavior are also incompletely hydrated in the unbound state because they typically feature narrow lipophilic clefts not unlike that of MUP (see ref 39 for a recent example). Desolvation costs are also the likely cause why some ligands that seem to fit into a binding site cannot experimentally be confirmed to be inhibitors. An ITC study on the interactions between simple benzamidines and trypsin concludes that the unfavorable desolvation of the oxyanion hole area upon binding of *p*-*tert*-butylbenzamidinium causes the observed complete loss of binding affinity for this molecule.²⁸

From these studies it becomes clear that carefully probing the hydration state of a protein binding pocket in the unbound state should be a standard element of structure-based design, as it will likely point out regions where most binding energy can be gained. Failure to match key hydrophobic areas with appropriate ligand moieties can have a severe impact on binding affinity. Figure 2 shows that an optimized factor Xa inhibitor is rendered virtually inactive when the key interacting group in the S4 pocket is replaced by hydrogen.⁴⁰ Not only does the isopropyl group optimally interact with the S4 pocket (see Hydrophobic Interactions) but its removal leads to a very unfavorably solvated state of the pocket^{41,42} that is likely the main reason for the dramatic loss of affinity.

Structural Water. Any ligand binding event displaces water molecules from the binding site. In structure-based design, most of these are never explicitly considered because they are highly disordered and therefore rarely crystallographically observed.⁴³ Enzyme binding sites are in fact characterized by easily displaceable water, as shown by Ringe in her seminal work on transferring protein crystals to organic solvents.⁴⁴ Those water molecules that are observed need to be carefully analyzed; they might be replaceable or they might be considered as part of the protein structure.⁴⁵ Analyses of high-resolution crystal structures by Poornima and Dean showed that protein–ligand contacts are often mediated by water molecules situated in deep grooves in the binding site and forming multiple hydrogen bonds with both binding partners.⁴⁶ Relibase+, a database and query system for analyzing protein–ligand complexes, contains a module that allows a rigorous assessment of water structure in binding sites.⁴⁷

The release of a water molecule from a rigid environment should be entropically favorable. In a classic contribution, Dunitz has estimated the upper limit of the entropy gain for transferring a water molecule from a protein to water to be 2 kcal/mol at room temperature.⁴⁸ To reach the 2 kcal/mol limit, a water molecule will have to be very tightly bound in a rigid protein structure. The entropy gain in releasing the water molecule will then be offset by a loss in enthalpy, and conversely, less tightly bound water molecules might approach or even exceed the entropy in bulk water. It has been observed that even rather tightly bound water molecules can retain a very high amount of residual mobility.^{49,50} Furthermore, protein flexibility may be significantly affected by water binding. Cases are known where proteins become more rigid⁵¹ or more flexible⁵² upon water binding. So how should one assess which water molecules are replaceable?

Various flavors of molecular dynamics and free energy calculations have been applied to study this problem. Essex et al., using thermodynamic integration calculations in Monte Carlo simulations, found that the calculated binding free energies for individual water molecules allowed a rough classification into those displaced by ligands and those conserved across protein–ligand complexes; the conserved ones are more tightly bound.⁵³ Li and Lazaridis computed the thermodynamics of water displacement in concanavalin A–carbohydrate complexes and concluded that “the final outcome of water displacement is sensitive to the details of the binding site and cannot be predicted by simple empirical rules”. The complexity of the contributions of specific water molecules to ligand binding has recently been re-emphasized in a comprehensive study by Jorgensen et al.⁵⁴

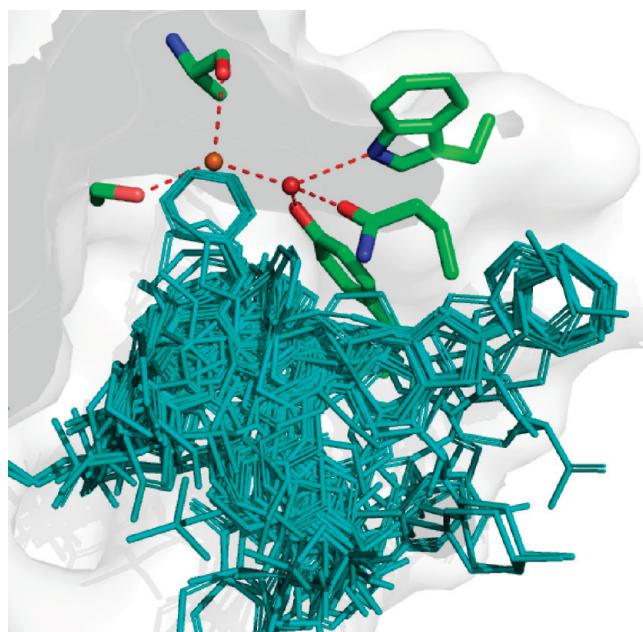

Figure 3. Overlay of representatives of 15 different PDE10 inhibitor classes. Two water molecules are deeply buried in the binding site of the apo form and are hydrogen-bonded to two (left) and three (right) protein residues, respectively. Only the less tightly bound water molecule has been displaced by PDE10 inhibitors so far.

Extensive computer simulations are not generally feasible in a fast-paced drug discovery environment, but simple geometric parameters describing the immediate protein environment of a crystallographic water molecule can serve as a useful guide to estimate whether it is displaceable by a ligand moiety.⁵⁵ In our hands, a simple geometric rank function based on the distances and angles of neighboring donor and acceptor atoms in the protein, developed by Kellogg and co-workers, has served as a practically useful metric.⁵⁶ Water molecules with high ranks should be regarded as part of the binding site.^{57,58} These experience three or more hydrogen bonds with the local environment and are usually located in buried polar cavities. Replacement of an optimally coordinated water molecule will require very high design precision because otherwise the enthalpy loss might be hard to regain. In contrast, displaceable water molecules often participate in a water network without tight binding to the protein. More “sloppiness” in the design is allowed in these cases.

A number of studies allow a direct comparison between a ligand binding to a structural water and a very close analogue displacing it. A nitrile substituent has successfully been used as an isostere of a water hydrogen-bonded to a pyridine-like acceptor nitrogen in EGFR kinase⁵⁹ and p38 MAP kinase inhibitors⁶⁰ as well as in inhibitors of scytalone dehydratase.⁶¹ In all of these cases affinity was retained or even improved. In peptide inhibitors of iNOS,⁶² an amide and an amine functionality were independently replaced by the respective aminoxides and yielded equipotent inhibitors replacing a water molecule bound by the heme carboxylates. In all of these cases no more than two hydrogen bonds are formed between protein and water, indicating nonideal coordination. Campiani et al. reported an instructive counterexample. They attempted to replace a water molecule in acetylcholinesterase by derivatives of huperzine and observed a dramatic loss in affinity.⁶³ The designed phenol ligands clearly would not reach the position of the water,

which in addition is firmly coordinated by three hydrogen bonds to the protein.

The binding site of PDE10 contains two buried water molecules that are hydrogen-bonded to each other and to two and three protein residues, respectively (Figure 3). This high coordination suggests a large enthalpic penalty for the removal of any of these. We found that the water molecule with almost ideal tetrahedral coordination has not been displaced by any known PDE10 ligand, while 1 out of 15 different inhibitor series was able to expel the less tightly bound water molecule.

Wherever possible, a comparison between water placements in multiple independently solved crystal structures should be made to minimize errors during the modeling of water sites in the refinement process.⁶⁴ Strongly bound water molecules are often conserved across multiple crystal structures. Alternatively, water sites have been predicted computationally through MD simulations⁶⁵ or empirical functionals.⁴¹ An increasingly important area of investigation is the analysis of entire water clusters. Understanding the hydration properties of subpockets within binding sites can be the key to understanding ligand binding, as exemplified by research on the OppA protein.^{66,67} Crystal structures of complexes between OppA and peptides of the general structure Lys-X-Lys reveal that certain water molecules adopt the same position independently of the nature of residue X. The strength of the interactions between these water molecules can help explain the binding affinities of the OppA-peptide complexes. tRNA-guanine transglycosylase is another protein in which a conserved water cluster has been carefully studied.^{68,69} Achieving a more general understanding of the properties of water clusters is a challenge for the future. For example, ring-shaped water clusters seem to be prominent in outer hydration spheres⁷⁰ and perhaps in purely hydrophobic binding pockets,⁷¹ as they benefit from cooperativity of their hydrogen bonds.⁷²

Repulsive Interactions. An important element of the design process is the analysis of repulsive interactions one may have artificially generated upon modifying experimentally determined coordinates of a complex in silico. This is even more critical if part of the protein is treated as flexible during a minimization step, since locally introduced strain can be absorbed by other parts of the structure and can be dissipated to such an extent that it becomes unrecognizable. It is therefore advisable to keep the protein rigid with the exception of only those parts that are known to adapt to ligands or to create alternative hypothetical low-energy states of a protein that are then kept fixed in the design process. The availability of multiple crystal structures of the same protein with different ligands is most useful here, as their overlays allow the identification of backbone movements and flexible side chains. Severe repulsive interactions are not observed in nature, so distances significantly below the shortest experimentally observed ones are to be avoided. General steric fit can be assessed through surface depictions of both binding partners. In addition, one may rely on general molecular mechanics terms or simple van der Waals distance criteria to analyze steric clashes. Conformations should be carefully checked; force field minimization often has the effect of achieving a good interaction at the expense of a strained torsion angle. Torsion angles are the softest conformation parameters and yet have the largest effects on geometry.⁷³

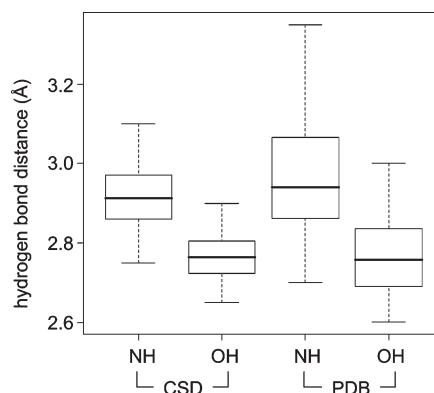

Figure 4. Box plots (box region corresponding to the central 50% of the distribution, dotted lines extending to max 1.5 times this interval) of hydrogen bond length distributions with NH and OH as donors: (left) CSD statistics; (right) PDB statistics. In the PDB, the distributions around roughly the same mean are significantly broader.

Specific Intermolecular Interactions

Hydrogen bonds are by far the most important specific interactions in biological recognition processes. Geometries of hydrogen bonds follow strict rules, which were among the first to be extracted from crystal structure databases. Interactions between NH and carbonyl groups,⁷⁴ interactions of hydroxyl groups with carbonyl, ether, and ester groups,⁷⁵ and hydrogen bonds to aromatic heterocycles⁷⁶ were studied in detail. Systems like Isostar⁷⁷ and Superstar⁷⁸ have proven useful for visualizing such interaction preferences. The spatial distribution of intermolecular contacts between carbonyl groups and NH donors has been converted to energy maps, highlighting commonalities and differences between ester and amide acceptors.⁷⁹ This approach has also been applied to protein structures, where good agreement was found between statistical analysis and quantum mechanical calculations.⁸⁰ Here we will not exhaustively cover the topic of hydrogen bonding but will present key facts and concepts.

Frequency distributions of classical hydrogen bond *distances* give rise to sharp peaks, allowing one to distinguish small differences in median distances. In the CSD, hydrogen bonds between amide C=O and OH have a median distance of 2.75 Å. With NH donors, the median distance increases to about 2.9 Å. Within binding site regions of the PDB, the same median distances are observed. PDB distributions are significantly broader but still clearly separated from each other (Figure 4). In theory, this means that a hydrogen bond should be within about ± 0.1 Å of its median observed distance. If this cannot be achieved in a relaxed state, the design should be modified. In practice, however, such rigid distance criteria can rarely be applied, since the adaptation of protein structure to a modified ligand is hard to predict. Furthermore, the coordinate precision of protein structures is much lower than that of small molecule crystal structures, and it varies considerably not only as a function of overall resolution.^{81,82}

We have analyzed the preferred geometries of a variety of acceptors and donors by searches in the CSD (see Figures S-1 and S-2 of Supporting Information). Even for the weakest acceptors (ether, sulfonamide), the median distance is shorter than the sum of van der Waals radii of the donor and acceptor heavy atom. Charged hydrogen bonds are considerably shorter than comparable uncharged ones. For example, the salt bridge between carboxylate and ammonium has a median

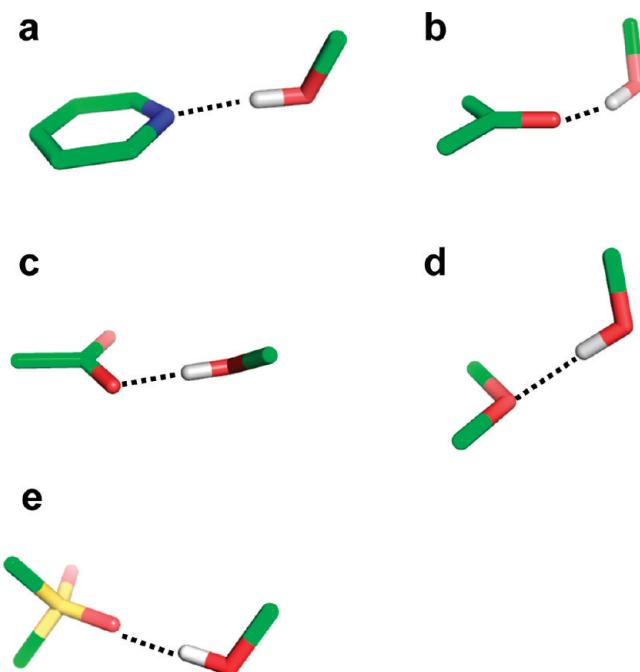

Figure 5. Schematic depiction of the most preferred geometries of hydrogen bond interactions with various types of acceptors: (a) pyridine nitrogen, (b) carbonyl oxygen, (c) carboxylic acid, (d) ether oxygen, (e) sulfonyl group.

distance of 2.79 Å. With a neutral amine as a counterpart, this distance increases to 2.83 Å. A hydrogen bond between amide carbonyl and amine is typically 2.9 Å long.

The *angular preferences* of hydrogen bonds are also quite pronounced. A number of typical geometries are shown in Figure 5. The angle donor–hydrogen···acceptor is generally above 150°. Only ethers, which are rather weak acceptors, show a somewhat higher variability of this angle. Hydrogen bonds are generally formed along the direction of the free electron pair of the acceptor atom. For example, the preferred angle C=O···H has its peak at 120°, corresponding to the lone pair direction of the carbonyl oxygen. This mnemonic rule does not hold for sulfonyl groups, where hydrogen bonds along the S=O axis are slightly preferred. For sulfonyl and carboxylate groups, one needs to further distinguish between syn and anti directions with respect to the second oxygen atom. The syn orientation is preferred over anti in both cases. The interaction with the syn lone pair is almost always an asymmetric one with the donor atom interacting with only one of the oxygen atoms.⁸³ The last geometric feature to be monitored is the deviation of the hydrogen bond from the acceptor plane in the case of acceptors comprising π systems (aromatic ring plane or the plane formed by carbonyl and its two substituent atoms). The deviation from the acceptor plane is generally below 25–30°.

While the preferred geometries of hydrogen bonds are easily defined, their contribution to affinity is highly context-dependent. Davis and Teague,⁸⁴ Kubinyi,⁸⁵ and Ladbury⁸⁶ have collected many illustrative examples. Hydrogen bonds always convey specificity to a recognition process but do not always add much binding free energy. Desolvation of the donor and the acceptor must occur for the hydrogen bond to form, such that the effects of hydration and hydrogen bond formation nearly cancel out.⁸⁷

Thus, a primary question in molecular design should be which donors and acceptors need to be satisfied and not how

more hydrogen bonds can be formed. Analyses of entire protein structures showed that both NH and CO groups form hydrogen bonds to a very large percentage,⁸⁸ in particular in high resolution crystal structures, and the remaining cases can usually be explained by artifacts of the crystal structures or inadequacies of the search methods.⁸⁹ The number of observed hydrogen bonds clearly increases with decreasing solvent accessibility.⁹⁰ There is evidence, however, that not satisfying a hydrogen bond donor in a protein, i.e., burying a donor in a desolvated state, has more drastic energetic consequences than not satisfying an acceptor. Homas et al. report a penalty of 4.3–5.3 kcal/mol for a hydroxyl group binding in a hydrophobic pocket, due to the cost of desolvation.⁹¹ Relatively little loss of free energy is incurred upon removal of a hydrogen bond to a backbone carbonyl group. Bartlett and co-workers showed that replacements of NH by a methylene group hardly reduced the binding affinity of peptidomimetic thermolysin inhibitors, whereas the replacement of NH by oxygen allowed a dramatic loss in affinity by 4 kcal/mol.⁹² The binding of acylated tripeptides and their analogues to vancomycin gives a similar picture: replacement of NH by methylene leads to a loss of 1.5 kcal in binding free energy, replacement by oxygen to a loss of 4.1 kcal/mol.⁹³ In a series of Chk1 inhibitors, a reduction in binding affinity of 1.4 kcal/mol was observed in changing a pyrrole to a furane ring where in both cases the heteroatoms point toward the Cys87 backbone carbonyl group. As in the previous two examples, this loss of affinity is probably mostly due to the introduction of a repulsive O···O interaction rather than due to the removal of the NH···O hydrogen bond.⁹⁴

A look at the world of kinase inhibitors confirms this trend. The vast majority of kinase inhibitors with any direct hinge interactions form a hydrogen bond to the backbone NH situated at the center of the hinge strand. Where this is not the case, the backbone NH is usually solvated (see, for example, PDB code 1zz2 and ref 95). We are aware of only a single ligand where the backbone NH has no good counterpart: 4,5,6,7-tetrabromobenzotriazole forms two halogen bonds to the flanking backbone carbonyl groups but no direct interaction with the NH group (PDB code 1p5e). In contrast, hinge binding ligands often leave one backbone carbonyl group in a desolvated state without a compensatory interaction. PDB entries 3blr and 3fmd may serve as examples.

So far, we have neglected the fact that hydrogen bonds can vary quite considerably in their intrinsic strength. To a first approximation, this might be justified because a stronger hydrogen bond also implies higher desolvation costs, so the net free energy gain of a stronger hydrogen bond might be minimal. However, the wide variation of the free energy changes associated with hydrogen bonds indicates that this picture is too simplistic. Just like solvent accessibility, the geometry of hydrogen bonds and the nature of neighboring atoms are key parameters determining this free energy change; hydrogen bond strengths should be carefully assessed as well.

The propensities of many functional groups to form hydrogen bonds have been experimentally determined and tabulated by Abraham⁹⁶ and more recently by Laurence in the form of the pK_{BH}X scale, details of which have been reviewed in this journal.⁹⁷ Where experimental data are not available, acceptor strengths can be obtained from quantum chemical calculations.⁹⁸ Calculated acceptor strengths and those derived from IR spectroscopy generally correlate well with each other, indicating that the entropic component of

Table 1. Hydrogen Bond Acceptor Strengths (pK_{BHX} Scale) and Frequencies Observed in the CSD for Selected Hydrogen Bonds Types

	typical acceptor strength (pK_{BHX})	frequency of hydrogen bond to OH [%]
Acyclic Oxygen Acceptors		
amide	2.2–2.6	48
ketone	1.1–1.2	39

N-alkylated imidazole N	2.72	41
pyridine N	1.86	32
oxazole N	1.67	30
pyrazine N	0.92	25
furan O	−0.4	0.5

hydrogen bond formation in water is relatively constant across acceptors.

What can be learned from such parameters? First, acceptor strengths are not directly related to proton basicities. The most basic center in a molecule is not necessarily the best acceptor. An appreciation of acceptor strengths can thus lead to a better understanding of desolvation effects and interaction preferences, for example, of more complex heterocycles. Second, although rarely reported, cases are known where acceptor (or donor) strengths correlate with affinity, leading to important insights into SAR.^{99,100} Finally, these values can help design molecules with better overall properties, for example, by modulating the nature of solubilizing groups. There is good general agreement between statistical likelihoods of hydrogen bond formation in the CSD and acceptor strengths. For example, nitrogen acceptors in aromatic heterocycles are more frequently observed to form hydrogen bonds in the CSD than oxygen acceptors,¹⁰¹ in agreement with pK_{BHX} data.

Our CSD searches also indicate a qualitative agreement between hydrogen bond frequencies and pK_{BHX} acceptor strengths, as shown by the data in Table 1 for acyclic oxygen atoms as acceptors and for a selection of planar heterocycles. For the CSD searches, very generic substructures have been used, and so the results should be taken as a qualitative and average property of each functional group. In addition to the nature of the functional group, many factors influence acceptor strength. For example, cyclic amides (lactams) and cyclic ethers are significantly stronger acceptors than acyclic ones. Electron-donating substituents at the aromatic rings increase the acceptor strength, while electron-withdrawing ones decrease it. Aromatic ethers such as anisole are weaker acceptors than aliphatic ones. Because of its extremely low propensity to form hydrogen bonds, diphenyl ether might even be regarded as a bioisostere of diphenylmethane.

Only 30% of the sulfones and sulfonamides form hydrogen bonds. This raises the question of which type of interaction this functional group prefers. In the CSD, we find that about 80% of the SO_2 groups are in proximity (3.3–3.9 Å) to an aliphatic carbon atom (in our queries we used any methylene unit $-\text{CH}_2-$ as a prototype hydrophobic group). In the PDB, 39% of the ligand sulfonyl groups are found to form a hydrogen bond with either a protein donor or a structural water molecule, while 74% are located in or close to van der Waals distance (3.3–3.9 Å) to an aliphatic group. Notably, of the sulfonyl groups situated in a hydrophobic environment in

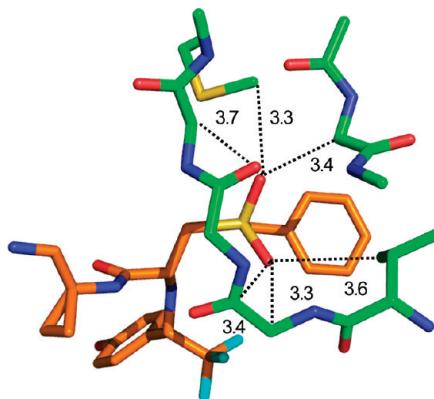

Figure 6. Closest interactions (distances in Å) formed by the sulfonyl oxygen atoms of a cathepsin S ligand within the active site (PDB code 2fra). Most side chains have been omitted for clarity.

the PDB, only 36% are found to interact simultaneously as a hydrogen bond acceptor but 79% of the hydrogen-bonded sulfonyl groups are found to interact simultaneously with a hydrophobic group. These findings clearly indicate a dual character of the weakly polar sulfonyl groups as a hydrogen bond acceptor and as a hydrophobic group. An example of the types of hydrophobic environments that sulfonyl groups are found in is given in Figure 6, which depicts a section of the binding site of the ligand CRA-27934 within the cathepsin S cocrystal structure (PDB code 2fra). The sulfonyl group forms several van der Waals interactions with nonpolar atoms and forms weak hydrogen bonds with $\text{C}\alpha\text{-H}$ donors. Further illustrative PDB examples include complexes of FK506 binding protein (1j4h) and phenylethanolamine *N*-methyltransferases (2onz). Hydrogen-bonded sulfonyl groups are prominent in cocrystal structures of matrix metalloproteinases (e.g., 3ehx).

One further aspect of hydrogen bonds requires the attention of the designer. Hydrogen bonds are rarely isolated interactions but are strongly influenced by additional polar atoms in the vicinity. Hydrogen bonds can mutually reinforce each other in networks. This is observed for aligned hydrogen bonds in protein secondary structures.¹⁰² Calculations on biotin-bound streptavidin indicate that cooperative hydrogen bonding may be one source of the particular strength of this complex.¹⁰³ Ring-shaped water clusters owe their stability to cooperative binding.⁷² The stacking of multiple β strands in amyloid fibrils has been, in part, ascribed to cooperative hydrogen bonding¹⁰⁴ in a way reminiscent of the association of urea molecules in nonpolar solvents.¹⁰⁵ Also, one should consider that branched hydrogen bonds are common in protein–ligand interfaces.¹⁰⁶ Hydrogen bonds with suboptimal geometries may be stabilized by additional partners that help to satisfy the total hydrogen bonding potential. Before labeling a particular interaction as “weak” because of its geometry, one should therefore assess its environment. It will be important to learn to recognize and to prospectively apply more complex hydrogen bonding patterns¹⁰⁷ that can be derived from crystal structure analysis. In this respect, materials science and supramolecular chemistry can fertilize the area of structure-based drug design, for example, through tools like the Cambridge Crystallographic Data Center’s Mercury.¹⁰⁸

Neighboring acceptor and donor groups can also weaken hydrogen bonds. Originally formulated by Jorgensen,¹⁰⁹ the “secondary electrostatics hypothesis” was soon confirmed by Zimmerman¹¹⁰ and is now widely accepted. Hydrogen

bonds to model peptides in the extended (C5) conformer are weakened by the proximity of the neighboring carbonyl oxygen to the NH donor.¹¹¹

While the hydrogen bond distances of salt bridges are shorter than those between neutral motifs, indicating stronger interactions, this does not necessarily translate into more favorable binding free energies. The contribution of charge-assisted protein–ligand hydrogen bonds to binding depends critically on the protein environment. Theoretical and experimental studies of solvent-exposed salt bridges reveal little free energy gain for the pairing of monovalent ions.¹¹² We are not aware of any example in which the formation of charge-assisted hydrogen bonds on the surface of the binding site of a complex has led to significant affinity improvements. This can be rationalized with the high solvation free energy of solvent exposed charged protein residues, which needs to be compensated by ligand binding. In contrast, a number of SAR examples exists in which charge-assisted hydrogen bonds are crucial binding hot spots. Common to these is that the interacting protein motif is at least partially buried and held in position by other interactions to surrounding residues. A textbook example is the critical salt bridge between Asp189 at the bottom of the S1 pocket of trypsin-like serine proteases with benzamidine inhibitors, where removal of the amidine group or reduction of basicity strongly reduces activity. More recently, it was found that the introduction of a 2-amino group in *lin*-benzoguanine as a ligand of tRNA-guanine transglycosylase leads to a 50-fold lower K_i .¹¹³ The modified ligand forms a cooperative charge-assisted hydrogen bonding network involving a part of the protein backbone and a more remote glutamate side chain (PDB code 2z7k). In a series of zanamivir analogues binding to neuraminidase, it was found that a positively charged amino group was roughly 30-fold more active than a neutral hydroxyl substituent.¹¹⁴ This substituent bridges two Glu and Asp side chains with formal negative charges providing additional electrostatic stabilization (PDB code 1bj1). Because of the long-range character of charged interactions, not only the direct protein–ligand contacts but also the influence of more distant protein charges should be considered when designing charge-assisted hydrogen bonds.

Weak Hydrogen Bonds. During recent years, an increasing amount of attention has been paid to weaker hydrogen bond interactions. This increased attention is a double edge sword: It sharpens the eye for interactions that previously went unnoticed, but it also increases the risk of overinterpretation. Numerous accounts of weak hydrogen bonds fall in the latter category,^{115,116} as they try to ascribe molecular recognition to selected observed interactions. Nevertheless, weak hydrogen bonds often do contribute to protein–ligand binding in a subtly directional fashion, and it is important to understand that they are, at the very least, not repulsive. The nature of weak hydrogen bonds has been extensively analyzed and reviewed by Desiraju.^{106,117} Here we will only briefly discuss the nature of a few representative cases.

Aromatic rings can act as acceptors of hydrogen bonds. Tsuzuki et al. have calculated the gas phase interaction between benzene and ammonia to be 2.2 kcal/mol, only slightly more attractive than that between benzene and methane (1.5 kcal/mol).¹¹⁸ In the most stable orientation, one NH vector is oriented perpendicularly to the ring plane at the benzene ring center. Likewise, 2-pyridone and benzene adopt a T-shaped NH···π hydrogen-bonded arrangement according to calculations and spectroscopic analysis of the

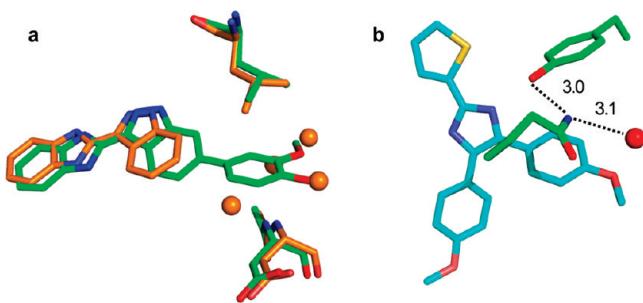

Figure 7. Structures referred to as NH···π interactions in the literature. (a) Chk1 kinase ligands. The orange structure has a K_i of $8.5 \mu\text{M}$ (PDB code 2c3l), and the green structure has a K_i of $0.026 \mu\text{M}$ (PDB code 2c3k).¹²² The additional phenyl ring displaces several water molecules, one of which was coordinated to the backbone NH below. The shortest NH···phenyl distance in the green structure is 3.4 \AA . (b) A PDE10 complex structure with a reported NH···π contact¹²³ where in reality the glutamine side chain forms two classical hydrogen bonds to water and a tyrosine. Distances are in Å.

supersonic-jet-cooled dimer.¹¹⁹ In proteins, interactions between NH donors and aromatic side chains are observed rarely and usually at long distances ($> 3.5 \text{ \AA}$). Clearly, an aromatic ring can only be a “reserve” acceptor for a strong donor. Tyr, Phe, and in particular Trp side chains interact more frequently with polarized CH groups as donors.^{120,121} There are few clear-cut cases where ligand phenyl rings accept hydrogen bonds from protein amide NH groups, and it is unlikely that these interactions are the root cause of affinity gains. Figure 7 shows two examples with reported NH···π contacts. Addition of a substituted phenyl ring to a weak Chk1 kinase ligand (Figure 7a) increased affinity from 8.5 to $0.026 \mu\text{M}$.¹²² The additional phenyl ring forms multiple interactions, including a contact to a valine side chain, and displaces several water molecules. One of these had been coordinated to the backbone NH below. Another NH···π interaction reported for a PDE10 complex¹²³ structure in reality does not exist: The glutamine side chain forms two classical hydrogen bonds to water and a tyrosine and thus fully satisfies the hydrogen bonding potential of the NH₂ unit (Figure 7b). While CSD statistics clearly indicate a preference of aromatic CH groups to be oriented above phenyl ring planes, there is no such preference for NH and OH groups. Figure 8 shows radial density plots of the distance above the aromatic plane of query hydrogen atoms versus their distance from the centroid in the plane (centroid shift). These two coordinates project the three-dimensional distribution of query atoms around the phenyl ring onto two dimensions with the centroid as the origin, facilitating visual inspection (details on the query setup and calculation of the radial distribution plots are found in Materials and Methods). Hydrogen atoms in XCH units polarized by neighboring heteroatoms (X = O, N) have a clear preference for interactions above the ring plane, whereas NH and OH groups rarely undergo π hydrogen bonds. The NH···π interaction itself might be stronger than the CH···π interaction, but this energy gain is overcompensated by a higher desolvation cost, since a strong donor will form significantly better interactions with a stronger acceptor than with a phenyl ring.

Interactions between CF and polar hydrogen atoms HX (where X = O, N) frequently occur in the PDB and CSD, even if such interactions cannot be classified as strong hydrogen

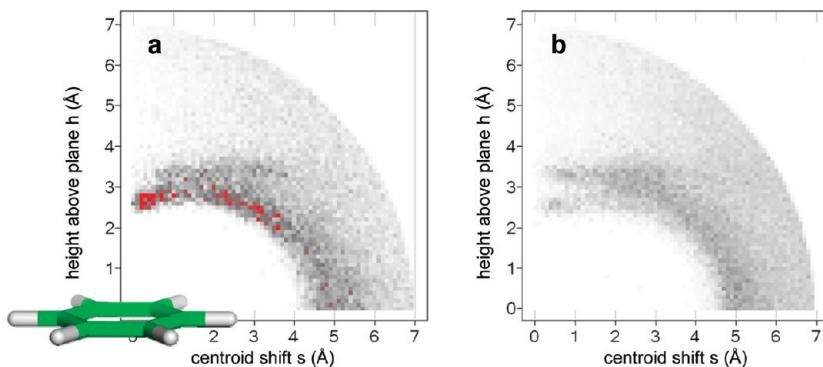

Figure 8. Radial distribution of hydrogen atoms around a phenyl ring (CSD statistics): (a) hydrogen bound to sp^2 carbon flanked by one or two heteroatoms (N, O); (b) hydrogen bound to O or N. Queries were set up as described in Materials and Methods. The phenyl ring in (a) is drawn roughly to scale and should serve as an interpretation aid for the in-plane (s) and above-plane distances (h). Darker gray corresponds to higher density; peaks above a numerical value of 70 are colored red.

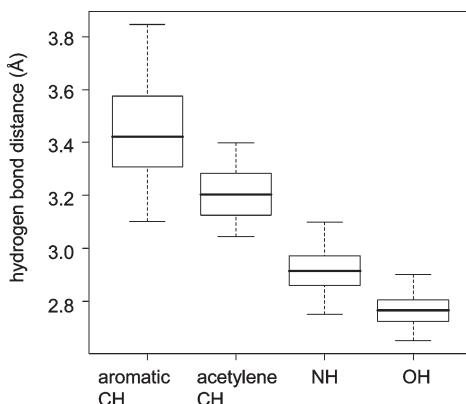

Figure 9. Box plots of hydrogen bond length distributions for the interaction between weak and strong donors and amide carbonyl oxygen as acceptor (CSD statistics). An increase in median hydrogen bond length and in breadth of the distribution is observed for decreasing donor strength.

bonds.¹²⁴ We have observed a thrombin inhibitor to change its binding mode upon fluorination of an aryl ring, such that a $\text{CF}\cdots\text{HN}$ interaction is formed.¹²⁵ In another study on factor VIIa inhibitors, a fluorinated phenyl ring was shown to act as an isostere of a pyridine.¹²⁶ An increase of affinity from 455 to 68 nM was observed in sitagliptin analogues binding to DPP-IV when going from 3,4-difluorinated to 2,4,5-trifluorinated triazolopiperazines.¹²⁷ The additional ortho-F forms interactions at 3.2 Å distance with NH_2 groups of Asn and Arg side chains (PDB code 1x70).

The weaker a hydrogen bond donor, the longer is the hydrogen bond distance and the broader is the distribution of the observed distances in crystallographic databases. This is illustrated in Figure 9 for the donor series OH, NH, acetylene CH, and CH in six-membered aromatic rings. The larger variation in median distances should not be overlooked in analyzing and designing structures. The most prominent weak donor is the CH group. In particular in kinase inhibitors, $\text{C-H}\cdots\text{O}$ interactions are frequently observed.¹²⁸ They play an equally important role in stabilizing planar conformations of linked heterocyclic systems. A team at Vertex working on GSK3 inhibitors has published an instructive study on the interplay between steric repulsion and classical and weak hydrogen bonds.¹²⁹ Often, CH groups bound to N or O atoms in aromatic heterocycles act as donors. The Ca-H unit of proteins is also a weak

donor. Calculations indicate that $\text{Ca-H}\cdots\text{O=C}$ interactions are about one-half the strength of an $\text{NH}\cdots\text{O=C}$ hydrogen bond.¹³⁰ Analysis of peptide X-ray structures show that the Ca-H unit can substitute for stronger donors.¹³¹ A close $\text{Ca-H}\cdots\text{F}$ interaction has been observed in a thrombin–ligand complex where the introduction of the fluorine atom led to a 5-fold affinity increase.¹³² Finally, cation– π interactions, discussed further below, might be regarded as hydrogen-bonded systems, since it is often not the cationic center itself, but an electron-deficient alkyl substituent, that forms the direct contact. Protonated histidines can also act as strong CH donors.¹³³

Halogen Bonds. In an analysis of crystal structure data published in 1986, Ramasubbu et al. concluded that “the halogen X in a C–X bond is capable of significant interactions with electrophiles, nucleophiles, and other halogens. The electrophiles approach X of the C–X “side on”, nearly normal to C–X, and the nucleophiles nearly “head-on” and behind the C–X bond.”¹³⁴ This observation, valid for the halogens Cl, Br, and I, is an ideal introduction to the following two sections on halogen bonds and multipolar interactions.

In contrast to fluorine, the heavier halogens have unique electronic properties when bound to aryl or electron withdrawing alkyl groups. They show an anisotropy of electron density distribution with a positive area (σ -hole) of electrostatic potential opposite the C–X bond.¹³⁵ In a molecular orbital framework, the origin of the σ hole can be explained from the fact that the three pairs of unshared electrons follow an approximate $\text{s}^2\text{p}^2\text{p}^2$ configuration forming a belt of negative charge around its central region, whereas the third p orbital along the C–X axis is distorted toward carbon, forming the C–X single bond. This leads to attractive interactions between C–X moieties and carbonyl groups or other classical H-bond acceptors, with a preference for linear C–X \cdots B arrangements. For example, distances below van der Waals radius (3.3 Å) between carbon-bound chlorine and sp^2 -hybridized oxygen almost exclusively occur with linear C–Cl \cdots O geometries.¹³⁶ The strength of halogen bonds increases with the size of the halogen atom. Because of its mostly electrostatic nature, it also depends on the electronegativity of the carbon substituents in the C–X partner and on the electron density of the binding partner.^{137,138} Halogen bonds are significantly weaker than hydrogen bonds. Ab initio calculations on formaldehyde–halobenzene dimers give gas phase interaction energies

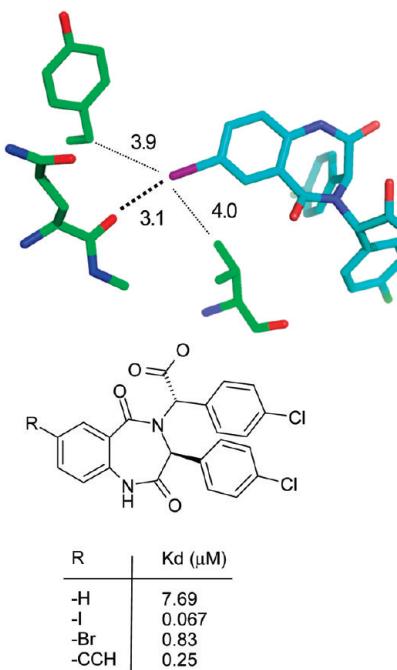

Figure 10. Iodine bond to a backbone carbonyl group in a HDM₅₃ domain crystal structure¹⁴⁵ (PDB code 1t4e, distances in Å).

below 2.5 kcal/mol, corresponding to the strength of CH \cdots O hydrogen bonds.¹³⁹ This is in accord with observations that halogen bonds involving iodine can displace less conventional hydrogen bond donors such as the C–H imine moiety.¹⁴⁰ QM/MM calculations on ligand–enzyme complexes¹⁴¹ cannot be expected to give meaningful values because halogen substituents typically form multiple interactions besides a halogen bond and because desolvation effects are not accounted for.

A large amount of structural and SAR data proves the existence of halogen bonds both in small molecule complexes and in protein–ligand complexes.^{142,143} Typically, replacement of hydrogen by iodine leads to the largest affinity differences. A 200-fold affinity gain from H to I has been observed in a series of adenosine kinase inhibitors¹⁴⁴ (PDB code 1lij), whereas Cl only led to a 34-fold affinity increase. A 100-fold increase in binding affinity was observed in a class of HDM2 inhibitors. Figure 10 shows that the closest contact between iodine and protein is formed by a carbonyl oxygen, whereas other van der Waals contacts are significantly longer. Note that iodine could be replaced by an acetylene substituent, leading to 4-fold lower affinity.¹⁴⁵ Acetylene and iodine substituents are comparable in length, and the affinity data suggest again that a halogen bond to iodine is comparable in strength to a weak hydrogen bond. A 300-fold affinity difference upon iodine substitution was observed in a series of HIV RT inhibitors.¹⁴⁶ In this series, the carbonyl oxygen of Tyr188 forms a halogen bond with an iodine substituent. In a high resolution structure, this carbonyl oxygen is observed to bend slightly toward the iodine, although not enough to abolish a β -sheet hydrogen bond with the Tyr181 nitrogen.¹⁴⁷ In the PDB it is not uncommon to find carbonyl groups forming both a halogen bond and a hydrogen bond. Calculations on model systems indicate that energies of halogen bonds to amide carbonyl groups are largely independent from simultaneously formed hydrogen bonds.¹⁴⁸ Affinity gains by iodine substitution drop with longer I \cdots O

distances, as observed, for example, in a series of BACE inhibitors¹⁴⁹ (PDB code 2iqg), where the affinity gain was only 25-fold.

In spite of the fact that halogen bonds formed by chlorine are usually much weaker, they can play a unique role in some complexes. The broad spectrum bactericide triclosan inhibits the FabI (enoyl reductase) component of bacterial fatty acid synthesis.¹⁵⁰ Complex structures with several enoyl reductases have been solved, and all show the same binding mode of triclosan. One chlorine is situated at the outer rim of the active site and interacts almost linearly at a distance of 3.3–3.5 Å with a backbone C=O. Strikingly, an extensive synthetic program directed at replacing this chlorine atom by both lipophilic and hydrogen bonding substituents did not lead to compounds with higher potency against *P. falciparum* enoyl reductase.¹⁵¹

We conclude that halogen bonds are weak but specific interactions that can lead to clear gains in binding affinity. They belong to the arsenal of structure-based design tools just like weak hydrogen bonds and, like these, have the advantage that they are associated with a lower desolvation cost than classical hydrogen bonds.

Orthogonal Multipolar Interactions. This particular interaction motif, characterized by a close orthogonal contact between two dipolar functional groups, has only recently received detailed attention.¹⁵² Note that in a completely orthogonal arrangement between two dipoles, the actual dipole contribution to interaction energy is zero such that higher order electrostatic and dispersion terms must be responsible for the attractiveness of the interaction. The disappearance of the dipole term may turn a repulsive electrostatic interaction into an attractive one. Manas et al. provide an instructive example involving a nitrile interacting with divalent sulfur.¹⁵³

Fluorine substituents are sometimes found at short distances (3.0–3.7 Å) and orthogonal to carbonyl carbon atoms. This arrangement is not the most frequent fluorine interaction observed in the PDB.¹⁵⁴ Investigations of a model system in chemical double mutant cycles confirmed the weakly attractive nature of the orthogonal C–F \cdots C=O interaction, with a contribution in binding free enthalpy in apolar environments of $\Delta\Delta G = -0.2$ to -0.3 kcal/mol. Multiple SAR examples have shown that increases in binding affinity can be obtained when this interaction is present.¹⁵⁵ Elastase is known to bind peptidic inhibitors with trifluoracetyl groups much more strongly than those containing acetyl groups,¹⁵⁶ and the corresponding X-ray structures feature three orthogonal CF \cdots C=O contacts.¹⁵⁷ A similar effect has been observed in the SAR of abl kinase inhibitors. In the active site pocket, the CF₃ group of nilotinib forms one interaction orthogonal to an amide besides two further contacts to the imidazole NH of a histidine as well as an isoleucine side chain¹⁵⁸ (Figure 11a). The CF₃ derivative is over 5-fold more active than the corresponding methyl derivative in an autophosphorylation assay.¹⁵⁹ Many classes of p38 MAP kinase inhibitors typically contain a phenyl ring in the lipophilic back pocket of the ATP binding site situated behind the gatekeeper residue.¹²⁵ A Merck team working on kinesin spindle protein¹⁶⁰ reports a dramatic boost in affinity upon fluorine substitution (Figure 11b), again with one of the two fluorine atoms interacting orthogonally with an amide bond. It should not be assumed that this increase in binding free energy can be ascribed to the interactions formed by fluorine only.

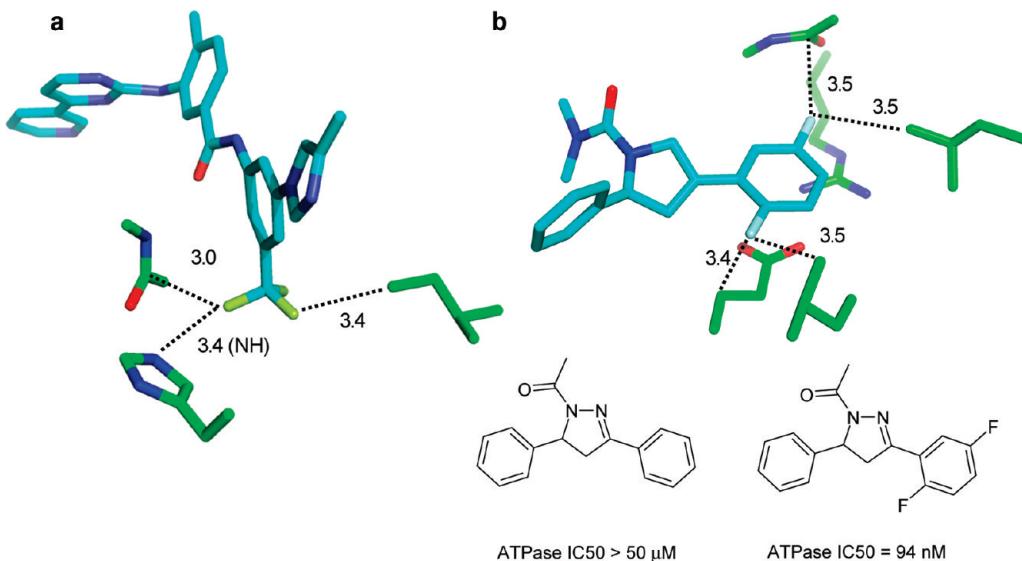

Figure 11. (a) Fluorine interactions in the complex between nilotinib and abl kinase (PDB code 3cs9).¹⁵⁹ (b) Kinesin spindle protein structure (2fl6) and activity data of two closely related inhibitor structures.¹⁶⁰ Distances are in Å.

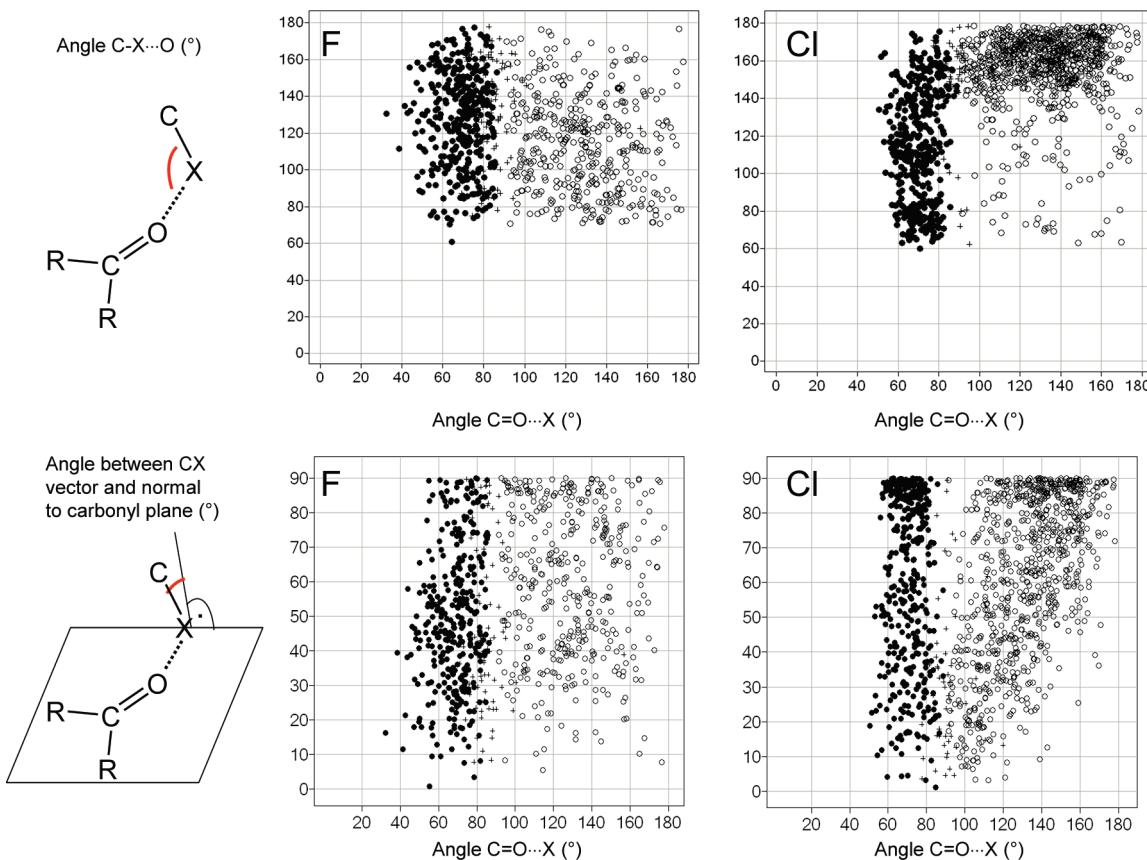

Figure 12. Occurrence of close contacts between F (left) and Cl (right) atoms and carbonyl groups in the CSD. Scatter plots show two different angle distributions. Points are categorized by their distance to the carbon and oxygen atoms of the C=O unit: (●) close contact between halogen and carbonyl C (< 3.3 Å for F, < 3.5 Å for Cl); (○) close contact between halogen and carbonyl O (< 3.1 Å for F, < 3.3 Å for Cl); (+) both close contact criteria satisfied.

Large components might be due to changes in residual mobility and desolvation. Still, the examples show the value of fluorine scans and in particular its targeted use in “fluorophilic” pockets.

Since halogens can interact both with the oxygen and with the carbon atoms of carbonyl groups, forming halogen

bonds and multipolar interactions, respectively, it is instructive to look at the relative propensities of both interactions in the same context. Figure 12 shows results of CSD searches between carbonyl groups and halogens, where either the halogen–carbon or the halogen–oxygen distance is below van der Waals contact. Fluorine does not have an orientation

preference, and the distinction between close contacts to carbonyl C and O seems somewhat arbitrary. CF bonds approach carbonyl centers from any direction. For Cl, the scatter plot divides into two distinct distributions for halogen bonds and multipolar interactions. Both types of contacts occur roughly with the same frequency. Chlorine does form multipolar interactions with carbonyl groups as fluorine does but shows a tendency for the C–Cl bond to be parallel rather than orthogonal to the amide plane, a consequence of the anisotropic distribution of electron density around the Cl atom. For clarity, Figure 13 shows the two preferred orientations of C–Cl vectors with respect to carbonyl groups. We have repeated these searches for bromine and iodine and find qualitatively similar distributions as for chlorine, with an increasing shift toward more halogen bonds and fewer side-on interactions. Analogous distributions extracted from the PDB are so much more scattered that a clear orientation pattern is not recognizable anymore (data not shown).

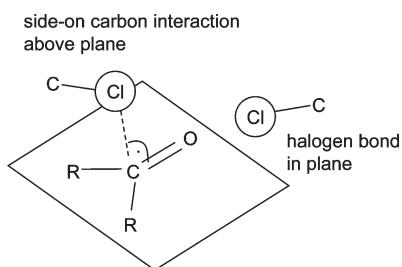

Figure 13. Preferred interaction geometries between chlorine and carbonyl groups derived from the CSD queries in Figure 12.

Halogens and Aromatic Rings. Various groups have analyzed crystallographic data on interactions between aromatic rings and halogen substituents, arriving at partially contradictory conclusions. On the basis of CSD searches, Schneider et al. observe a preference for $\text{CH}\cdots\text{halogen}$ interactions but often with significant van der Waals contacts to the π system, and they do not explicitly distinguish between fluorine and the heavier halogens.¹⁶¹ A similar CSD study by Prasanna and Guru Row even concludes that the propensity for the formation of $\text{CX}\cdots\pi$ interactions is higher in the case of fluorine than other halogens,¹⁶² in stark contrast to a study of fluorine interactions in the PDB.¹⁵⁴ Yet another study focused exclusively on interactions between fluorine and hydrogen bond donors, including very weak ones.¹⁶³ More recently, the attractive nature of interactions between heavier halogen substituents and aromatic rings has been emphasized, in particular in the context of serine proteases¹⁶⁴ and reviews on halogen bonding.¹⁴³ Unfortunately, the cited studies are not suitable to derive a clear picture of the orientation preferences and interaction energies of halogens around aromatic rings, since they suffer from one or more technical deficiencies: a focus on one type of interaction instead of a consideration of the relative importance of all alternatives, the lack of differentiation between different moieties (e.g., halogen bound to aliphatic vs aromatic carbon), and the analysis of database searches by means of uncorrected one-dimensional frequency diagrams or scatter plots instead of probability densities.

The query results depicted in Figure 14 give a more holistic picture. The radial distribution plots of both F and Cl have in common that the probability density reaches a maximum in the plane of the aryl ring, peaking at a centroid-to-halogen

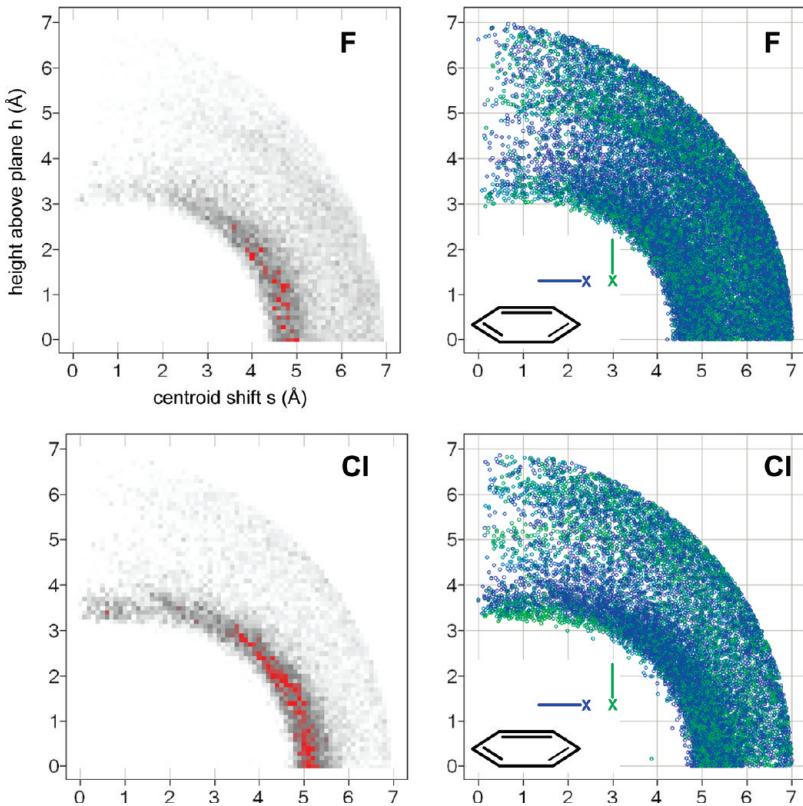

Figure 14. Radial distribution of fluorine atoms (top) and chlorine atoms (bottom) around phenyl rings (CSD statistics). Darker gray corresponds to higher density; peaks above a numerical value of 90 are colored red. Scatter plots of all hits for fluorine and chlorine (right-hand side) are colored by the angle between the phenyl plane and the C–X vector from blue (0° , in plane) to green (90° , orthogonal).

distance of 4.6–4.8 Å for F and of 4.9–5.2 Å for Cl. Thus, both Cl and F prefer, by a wide margin, interactions with CH over those with the π system. Gas phase calculations¹⁶⁵ and analyses of PDB structures¹⁵⁴ confirm this trend. Desiraju classifies CH \cdots halogen interactions as “very weak” hydrogen bonds.¹⁶⁶ In a crystallographic study of fluorinated benzenes, he observed H \cdots F contacts below van der Waals distance (\sim 2.6 Å) with increased fluorine content of the aryl ring, i.e., with increased hydrogen acidity. Also, short distances were only observed when CH \cdots F angles approach linearity. In our larger data set we observe this trend as well: Distances below \sim 2.6 Å are only observed with CH \cdots F angles above 120° (Figure S-3), indicative of a weak hydrogen bond character of this interaction.

Figure 14 (right-hand side) also shows scatter plots of the individual occurrences of halogen \cdots phenyl interactions, colored by the angle between the C–X vector and the normal to the aromatic plane. The hydrogen bond interactions do not show a dependence on the orientation of the C–X vector. There is, however, a clear trend for the C–Cl vector to be perpendicular to the aromatic plane at the closest observed distances from the centroid (3.2–3.4 Å) and directly above the plane. This coincides with a minor second maximum in the distribution function of Cl. Thus, a minor fraction of Cl atoms do form a halogen bond-like interaction with phenyl rings, with the σ -hole facing the π system. This trend is slightly more pronounced for Br, again with a peak clearly below van der Waals radius at 3.5 Å (Figure S-6). Note that the searches in Figure 14 included halogen atoms bound to sp³ carbon only. Supporting Information Figures S-4 to S-6 give an overview of all halogen interactions with phenyl rings, including halogens bound to aromatic rings. The difference in distribution between halogens bound to aliphatic and aromatic carbon clearly indicates that the driving force for the larger fraction of halogens situated above the ring plane is the stacking interaction between the two aryl rings and not the halogen interaction itself. Overall, the picture emerges that the orthogonal interaction between the heavier halogens and aromatic rings is attractive, as also confirmed by quantum chemical calculations in the gas phase,^{164,167} but that its energetic contribution to ligand binding in water has been overrated because of the high binding affinity gains observed with ligands containing chlorinated aromatic moieties as factor Xa and thrombin inhibitors. Depending on the nature of the ligand, the difference between a methyl group and Cl at the bottom of the S1 pocket can vary between 6-fold^{168,169} and 10-fold.¹⁶⁴ Desolvation effects are an unlikely cause of this difference.¹⁶⁹ However, the chlorine and methyl substituents form a significant number of additional contacts besides interacting with the tyrosine side chain that need to be taken into account in a full analysis. In particular for thrombin, the closest contact is often the formation of a halogen bond with a main chain carbonyl group (see, for example, PDB entries 1ta6 and 2jh5) and not with the tyrosine phenyl ring. Finally, chemical double mutant experiments in CDCl₃ gave repulsive values for all three halogens Br, Cl, and F interacting with the π faces of a phenyl ring. Fluorine had the most pronounced repulsive effect of about 0.7 kcal/mol.¹⁷⁰ These results are consistent with the crystallographic data and the use of a solvent less polar than water.

The above analysis of various halogen interactions highlights the fact that halogen atoms are not merely lipophilic appendages to fill hydrophobic cavities. In designing ligands,

we should be more aware of the detailed nature of lipophilic pockets to optimally exploit the weak directional nature of halogen interactions. The typical “good” halogen environment consists of multiple C–H \cdots X contacts. The more polarized (acidic) these groups are, the stronger the interaction is, up to the point where desolvation effects start to have a detrimental effect. Because of its high electron density and low polarizability, fluorine prefers dipolar interactions more strongly than the other halogens.¹⁷¹ The difference between typical fluorophilic and fluorophobic environments has become particularly apparent in a study on neprilysin inhibitors by the Diederich group.¹⁷² Any fluorine substituent at a phenyl ring in the S1' pocket led to a decrease in affinity, a result explained by electrostatically unfavorable close contacts of organic fluorine with the negatively polarized π -surfaces of surrounding aromatic amino acid side chains. In contrast, fluorination of the benzimidazole moiety of the ligand led to an increase in binding affinity. This ring system is located in a plane with three surrounding guanidinium groups of arginine side chains.

Hydrophobic Interactions. Many studies have shown that the single best structural parameter correlating with binding affinity is the amount of hydrophobic surface buried upon ligand binding. It holds for diverse sets of protein–ligand complexes,¹⁷³ for free energies obtained from ITC measurements,⁵ and for protein–protein interactions.¹⁷⁴ On the basis of oil/water partitioning experiments, the magnitude of the hydrophobic effect was estimated to be around 30 cal/(mol·Å²),¹⁷⁵ which is the equivalent of 0.7 kcal/mol or a 3.5-fold increase in binding constant for a methyl group. Essentially all empirical scoring functions used in docking and de novo design build on similar relationships, and already the visualization of matching molecular surfaces can be a useful tool in design.

This is, of course, a highly simplified view. First, we have seen above that details of (de)solvation and cooperative effects govern free energy gains through hydrophobic interactions. Second, optimal filling of a hydrophobic pocket is often achieved long before the van der Waals limit is reached. For synthetic host–guest complexes, it has been empirically established that optimal binding is observed when the guest occupies about 55% of the volume of the host.¹⁷⁶ The Diederich laboratory has investigated a series of plasmeprin II inhibitors with a wide variety of flexible alkyl chains binding into an induced lipophilic tunnel and could confirm the validity of the “55% rule” for this system.¹⁷⁷ These findings stress the importance of residual flexibility in binding events. Finally, we have seen above in the discussions on halogen interactions and weak hydrogen bonds that a simple distinction between “polar” and “unpolar” groups is not useful; there is a gray zone of weakly polar and directed interactions in between.

Particularly large gains in binding free energy of several kcal/mol per heavy atom can be obtained when a lipophilic protein pocket is optimally occupied by nonpolar ligand atoms.^{178,179} An instructive example stems from the optimization of interactions in the S1 specificity pocket of the serine protease DPP-IV which is composed of several hydrophobic Val, Trp, and Tyr side chains. Substitution of the meta-phenyl hydrogen atom by a –CH₂F moiety resulted in a 400-fold increase in binding in a series of aminobenzoquinolizine inhibitors.¹⁸⁰ Figure 15 illustrates the excellent fit of this substituent to the asymmetric S1 pocket, with five short hydrophobic contacts to the surrounding side chain atoms.

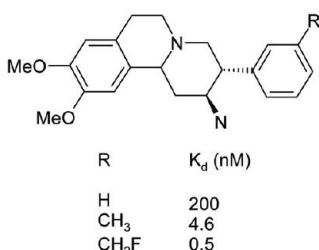

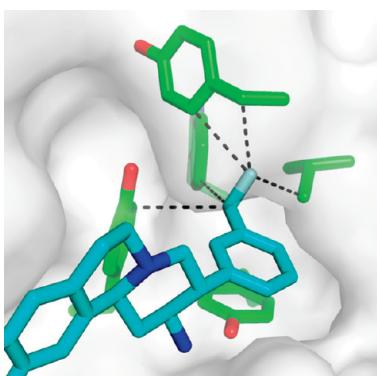

Figure 15. X-ray complex crystal structure of human DPP-IV with an aminobenzoquinolizine inhibitor ($R = \text{CH}_2\text{F}$) and affinity data for three derivatives.¹⁸⁰ The closest hydrophobic protein contacts of the CH_2F moiety (distances are less than the sum of van der Waals radius + 0.5 Å) are displayed (PDB code 3kwj).

The 9-fold difference in K_d between a methyl and a mono-fluoromethyl group can be attributed to the slightly bigger volume enabling a tighter fit and the roughly 2-fold higher interaction strength of fluorine compared to hydrogen. This example emphasizes the potential rewards that can be gained from the fine-tuning of hydrophobic shape complementarity.

As pointed out above, a significant amount of the large affinity gains imparted by hydrophobic interactions in narrow pockets is due to poor solvation of the pocket in the unbound state. Simulations on the hydration structure of different binding sites suggest that the buried water molecules are very poorly hydrogen-bonded.^{42,181} Recent experimental studies on cavity hydration indicate that small, completely apolar cavities might even be completely empty rather than occupied by a single water molecule.⁵⁰

Aryl–Aryl and Alkyl–Aryl Interactions. Aryl rings deserve special consideration in the context of hydrophobic interactions. Interactions with aryl-containing amino acids like Trp, Phe, Tyr, and His are ubiquitous in proteins,^{182–184} and they often expose their aromatic side chain to the binding site. The special shape and electronic properties of aromatic rings, which give rise to large polarizabilities and a considerable quadrupole moment, result in a set of preferred interaction geometries. For interactions between two π systems, the T-shaped edge-to-face and the parallel-displaced stacking arrangement are predominant. High-level quantum mechanical calculations of the dimerization energy of benzene predict these two arrangements to be isoenergetic ($D_e = -2.5$ kcal/mol),¹⁸⁵ with an absolute value in good quantitative agreement with experimental results ($D_e = -1.6$ to -2.4 kcal/mol).^{186,187} In protein structures, the parallel-displaced geometry is found somewhat more frequently than the T-shaped arrangement.¹⁸⁸

Introduction of substituents or insertion of heteroatoms into aromatic rings influences the relative propensities for

edge-to-face vs parallel-displaced arrangement. Some guidelines for the optimization of aryl interactions of a given geometry are summarized here, taken mainly from the comprehensive review of Meyer et al.:³⁵ Stacking arrangements of an electron-poor and an electron-rich aromatic ring profit from charge transfer. Stacking between electron-deficient rings is generally preferred over stacking of electron-rich ones. The preferred orientation of heteroaromatic rings is significantly affected by the alignment of positive and negative partial charges and molecular dipoles. Consideration of the detailed distribution of atomic charges and molecular electrostatic potentials is warranted here. The usefulness of electrostatic potential maps for the assessment of interaction strengths with aryl rings has been pointed out.¹⁸⁹ It should be noted, however, that such maps should not be interpreted as only reflecting local electron density. Through-space substituent effects can dominate.¹⁹⁰

The attractiveness of edge-to-face interactions can be increased when the interacting hydrogen atom is rendered more acidic, most effectively by introducing strongly electron-withdrawing substituents in ortho- and/or para-position. High-level ab initio calculations confirm this trend:¹⁹¹ The T-shaped interaction between benzene as a donor and fluorobenzene as the acceptor is ~ 0.3 kcal/mol weaker than that of the benzene dimer. With reverted roles (fluorobenzene para-H as the donor), the interaction becomes ~ 0.6 kcal/mol stronger relative to the benzene dimer.

Investigations of model systems led to the conclusion that aliphatic–aromatic and aromatic–aromatic edge-to-face contacts provide similar levels of stabilization.¹⁹² For T-shaped aliphatic–aromatic interactions there is computational and experimental evidence that the interaction energy increases with increasing acidity of the interacting CH unit. High-level ab initio calculations of dimer dissociation energies between benzene and ethane, ethylene, and acetylene, respectively, yield a clear correlation in which the more acidic sp-hybridized acetylene (-2.8 kcal/mol) is about 1 kcal/mol more tightly bound than the sp³-hybridized ethane (-1.8 kcal/mol).¹⁹³ Database mining in CSD and PDB for interactions of phenyl rings with methyl groups provides further support (Figure 16). While methyl groups connected to another sp³-hybridized carbon atom (Figure 16b) show a rather broad range of interaction geometries, the distribution of methyl groups bound to electronegative atoms is much more biased toward edge-to-face interactions (Figure 16a). This behavior is qualitatively reproduced in protein structures (Figure 16c). The stronger electrostatic interaction and directionality arising from electron-withdrawing substituents have also been found by model calculations on fluorinated alcohols.¹⁹⁴

Edge-to-face and π – π stacking interactions are not limited to (hetero)aromatic rings but can also be exploited with H-bonding arrays such as guanidinium–carboxylate ion pairs of Arg and Glu/Asp side chains or with the π faces of amide bonds. These motifs require hydrogen bonding interactions within the π -plane but are rather apolar and highly polarizable in a perpendicular direction. Interaction energies of intramolecular amide stacking were found to be competitive with nearest-neighbor hydrogen bonding in IR spectroscopic measurements of small model peptides.¹⁹⁵ In our own searches, we find the typical distance between the amide and aromatic plane to be in the rather broad range of 3.2–3.7 Å.

Several SAR examples from medicinal chemistry programs illustrate the points made above. The S4 binding pocket of the serine protease factor Xa is composed of the

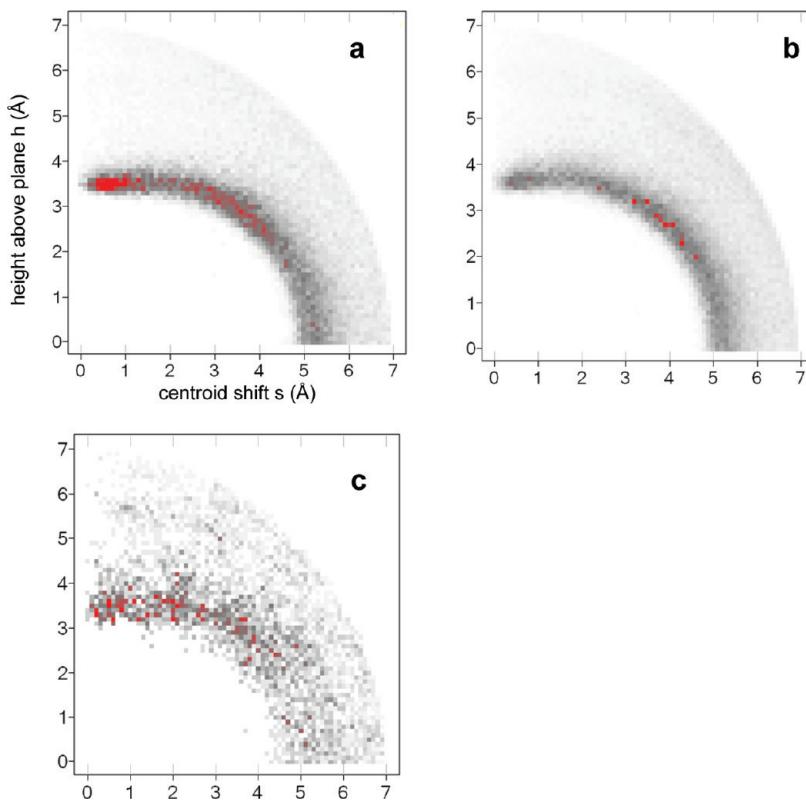

Figure 16. Radial distribution of carbon atoms around phenyl rings: (a) CH_3 bound to sp^3C (CSD statistics); (b) CH_3 bound to O or N (CSD statistics); (c) CH_3 bound to O or N (PDB statistics). Darker gray corresponds to higher density; peaks above a numerical value of 90 are colored red.

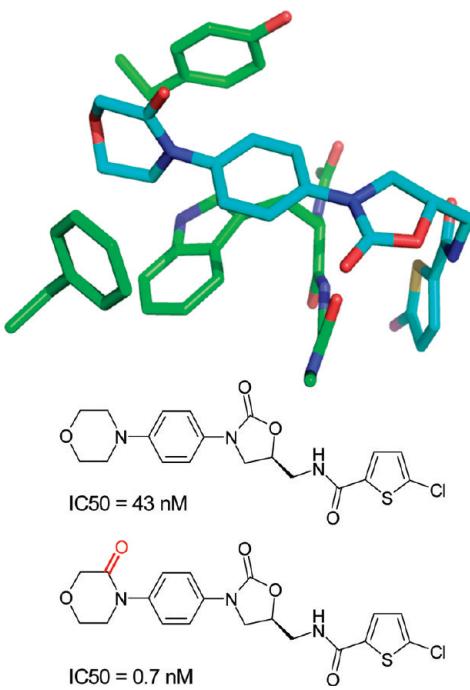

Figure 17. Structure and IC_{50} values¹⁶⁸ of factor Xa inhibitors (PDB code 2w26, distances in Å).

side chains of Tyr, Phe, and Trp and provides an “aromatic box” with opportunities for both edge-to-face and stacking interactions. The example in Figure 2 above clearly illustrates the strong gains in binding affinity that can be obtained by filling this pocket. Similarly, in a series of aminothiazole

inhibitors, a more than 300-fold gain in binding affinity could be achieved by inserting a 3-fluorophenylpyridone substituent into this pocket.¹⁹⁶ Both ligand aryl rings interact with the surrounding aromatic side chains. In the same target, a more than 60-fold lower IC_{50} value could be obtained by introducing a carbonyl group adjacent to the nitrogen atom of a morpholine ring.¹⁶⁸ As illustrated in Figure 17, the additional $\text{C}=\text{O}$ motif does not interact directly with the protein but exerts its beneficial effect through polarization of the ring CH_2 on top of Trp ($\text{C}-\text{Trp}$ distance: 3.5 Å), thereby increasing the $\text{CH}_2 \cdots \pi$ interaction as well as through conformational preorganization of a perpendicular arrangement to the adjacent phenyl ring. The beneficial effect of acidifying CH groups on top of an edge-to-face oriented phenyl ring can also be seen in a series of 2-anilinothiazolone steroid dehydrogenase inhibitors.¹⁹⁷ Introduction of a F-substituent adjacent to two aromatic CH groups in contact with a Tyr ring increases binding from $\text{IC}_{50} = 110 \text{ nM}$ to $\text{IC}_{50} = 17 \text{ nM}$ (PDB code 2rbe). Enhanced van der Waals contacts of the fluorine atom with a neighboring alanine side chain might also contribute. Finally, a drastic improvement in IC_{50} for inhibition of p38 MAP kinase was observed when inserting an oxygen atom between an amide and a methyl group (Figure 18).¹⁹⁸ The resulting methyl hydroxamate sits on top of a Phe aromatic ring and interacts additionally with a leucine side chain and through a weak hydrogen bond with a backbone carbonyl group. Acidification of the methyl protons through the attached hydroxamate certainly enhances the interactions with the Phe ring and the carbonyl acceptor. Similar to chlorine substituents, acidified CH groups can engage in both lipophilic and weakly polar interactions.

Cation– π Interactions. Cation– π interactions have been extensively studied in protein structures. Gallivan and Dougherty found that cation– π interactions are rarely buried¹⁹⁹ and that arginine side chains are more likely to form such interactions than lysine. Among the aromatic side chains, tryptophan is featured most prominently.²⁰⁰ Through a series of mutation studies, the interaction strength between a buried Trp and a Lys, Arg, or His side chain has been determined to range from –0.8 to –0.5 kcal/mol.²⁰¹ With increasing solvent exposure of the partners, the interaction energy dropped significantly. These values are consistent with several earlier studies performed with biological and synthetic receptor systems (summarized in ref 35). An instructive example is the complex structure of periplasmic lysine-, arginine-, and ornithine-binding protein (LAO). LAO binds lysine and arginine with the same affinity of about 15 nM.²⁰² The cationic centers of the amino acids

ligands are sandwiched between the aromatic rings of two Phe residues at about 3.6 Å distance (PDB codes 1laf and 1lst). In addition, several hydrogen bonds are formed between the guanidine and ammonium groups of the ligands and surrounding residues.

Arginine stacking interactions have rarely been utilized proactively. Detailed thermodynamic studies of galectin and lectin ligand complexes have been performed.^{203,204} A group at Vernalis found arginine stacking interactions to be an important factor in a series of 70 kDa heat shock protein inhibitors,²⁰⁵ an example of which has adorned the cover of this journal in 2009. Arginine stacking plays a role in nucleic acid binding sites. In particular adenine–arginine pair interactions are conserved within several protein families.²⁰⁶

The interaction between alkylammonium ions and aromatic rings can be seen as a special class of alkyl–aryl interaction. We have seen above that methyl groups favorably interact with the π face of aromatic rings when bound to an electro-negative atom. A (formally) positively charged nitrogen is a particularly strong electronegative substituent, and therefore, the direct interaction of an alkylated ammonium group with an aromatic ring leads to a strongly attractive interaction. Ammonium groups in medicinal chemistry are rarely permanently charged quaternary ions, so there is at least one proton on the nitrogen atom whose interactions need to be considered in the design process. Figure S-7 shows examples illustrating these effects. Carbamoylcholine binds to acetylcholine binding protein through a number of short contacts between the N-Me groups and Trp and Tyr side chains in the protein. Nicotine forms similar contacts with a different set of rings (Trp and the lower Tyr residue, contacts not drawn in Figure S-7a). In addition, the NH group of the nicotine cation forms a hydrogen bond to a backbone carbonyl group.²⁰⁷ The marketed acetylcholinesterase inhibitor donepezil binds to its target in a similar fashion, the NH group being solvated by a structural water molecule.²⁰⁸ The strong desolvation component of cationic interactions is highlighted particularly well in a recent study on factor Xa inhibitors by the Diederich group²⁰⁹ (Figure 19). Stepwise methylation of an ammonium substituent binding to the S4 pocket increased the binding affinity by 3 orders of magnitude. This leads to the conclusion that the desolvation cost of ammonium NH groups by far outweighs the energy gain of a direct NH·· π interaction, even if it is intrinsically attractive.²¹⁰ This is in agreement with studies on a β -hairpin model, where an enhancement of a cation– π interaction of about 0.2–0.3 kcal/mol per additional methyl group on a lysine was found.²¹¹

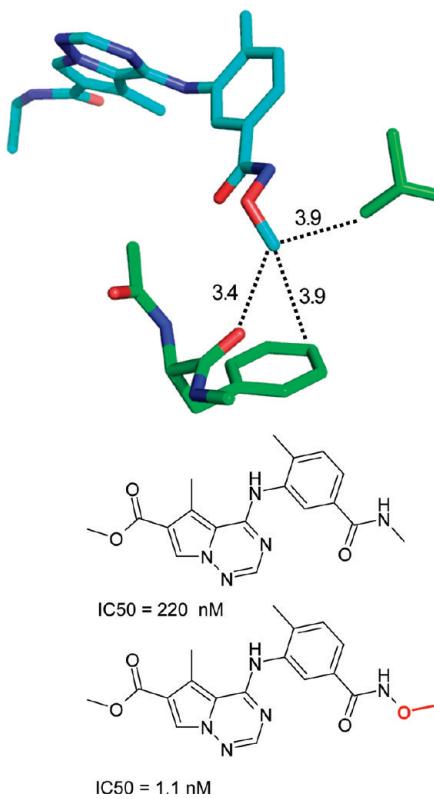

Figure 18. Effect of a methyl group on the IC_{50} of a p38 MAP kinase inhibitor¹⁹⁸ (PDB code 2rg5).

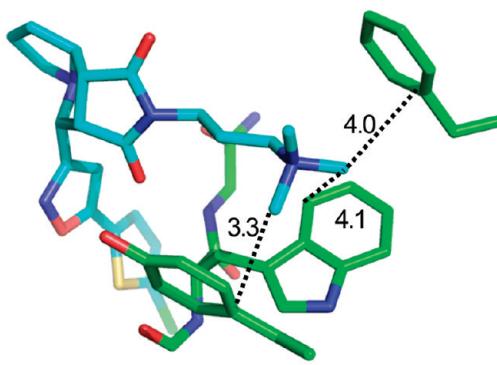

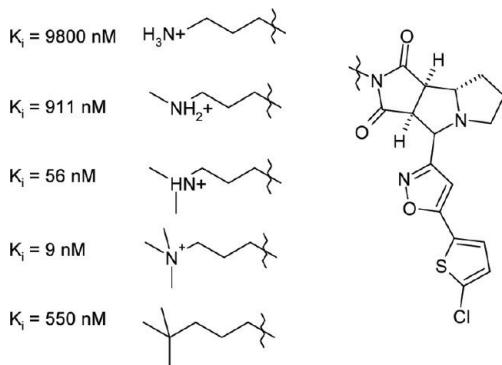

Figure 19. Example of cation– π interactions: a factor Xa inhibitor scaffold with systematically varied S4 pocket side chains (PDB code 2bok, distances in Å).²⁰⁹

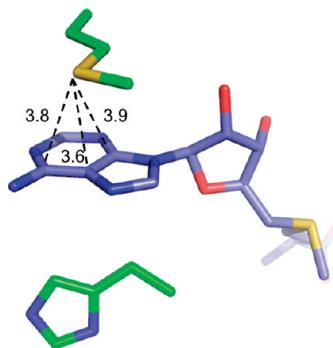

Figure 20. Interaction between methionine and adenine in the complex between *S*-adenosylmethionine and catechol-*O*-methyltransferase (PDB code 2cl5, distances in Å).

Interactions Formed by Sulfur. Divalent sulfur is a highly versatile atom. It is characterized by the ability to interact both with electron-poor and with electron-rich functional groups. Electron-rich ones tend to approach divalent sulfur along the extension of the C–S bond (σ^* direction), while electron-poor ones tend to approach it along the direction of the lone pairs.²¹² An example is the pair $\text{C}=\text{O}\cdots\text{SC}_2$, where the carbonyl oxygen acts as the electron-rich partner. Attractive carbonyl–sulfur interactions can have a strong influence on conformational equilibria.⁷³

Methionine side chains are both lipophilic and flexible. Both properties make them good targets in design, for example, in the binding sites of nuclear hormone receptors.²¹³ How do methionine side chains interact with aryl rings? Ab initio calculations have shed some light on the nature of these interactions. When benzene and either methanethiol²¹⁴ or H_2S ²¹⁵ are used as model systems, the lowest energy arrangement is that of an $\text{SH}\cdots\pi$ hydrogen bond, which may serve as a model for cysteine interactions only.²¹⁵ Arrangements in which the sulfur lone pairs point at the aromatic ring face are avoided. With dimethyl sulfide as a model system to represent the methionine side chain,²¹⁶ the most stable geometry is one in which the methyl groups interact with the π system, analogous to the interactions between methoxy groups and phenyl rings described above. Direct $\text{S}\cdots\pi$ interactions could not be reproduced.

Methionine–aryl interactions are quite frequent in protein structures. Pal and Chakrabarti found methionine as frequently as aromatic amino acids in the environment of the tryptophan indole ring (distance between ring carbon and S of <4.0 Å).²¹⁷ Out of 1276 methionine residues, 9% were found to be in contact with an aromatic edge and 8% with an aromatic face. Imai et al. found that $\text{CH}\cdots\text{S}$ interactions account for the majority of all methionine sulfur interactions (~40%) in the PDB. Close contacts between methionine sulfur and π systems occurred with a frequency of about 22%,¹²¹ including electron-poor π systems such as amides. In the CSD, Zauhar et al. found a pronounced preference for thioethers to form $\text{CH}\cdots\text{S}$ interactions in the plane of the aryl ring.²¹⁸ Our searches agree with these findings. In fact, the trend that sulfur atoms of thioethers are preferentially found in the phenyl ring plane and not above it is also visible in the corresponding PDB query (Figure S-8). Overall, it seems that with regard to phenyl ring interactions, divalent sulfur behaves like a weakly negatively polarized atom not unlike chlorine.

The binding sites of adenine rings (as part of enzyme substrates or cofactors) repeatedly feature methionine side

Table 2. Summary of Typical Interaction Distances of Selected Non-covalent Interactions^a

Interaction type	Typical distance range [Å]	
Hydrogen bonds	OH	NH
Carbonyl/sulfonyl O	2.7 - 3.0	2.8 - 3.1
Heteroaromatic N	2.7 - 3.0	2.8 - 3.2
Carboxylic acid O	2.6 - 2.8	2.7 - 3.0
Halogen bonds	Cl	Br
Carbonyl O	3.0 - 3.4	3.0 - 3.5
Multipolar interactions		
F ... carbonyl C	3.0 - 3.7	
Interactions with Aliphatic C		
F	3.3 - 3.9	
Cl	3.6 - 4.3	
Aliphatic C	3.7 - 4.4	
Sulfonyl O	3.3 - 3.9	
Divalent S	3.8 - 4.2	
Interactions with Aryl C	In plane	Above plane
Aromatic C ... divalent S	3.7 - 4.2	
Aromatic C ... F	3.3 - 3.7	
Aromatic C ... Cl	3.6 - 4.1	3.5 - 4.0
Aromatic C ... Br	3.7 - 4.2	3.5 - 4.1
Aromatic C ... $-\text{CH}_2-$	3.8 - 4.4	3.6 - 4.2
Aromatic C ... $\text{CH}_3\text{O}-$		3.4 - 4.0
Aromatic C ... CN^+		3.4 - 4.0
Aromatic C ... Amide-N		3.4 - 3.8
	Parallel displaced	Edge to face
Aromatic C ... aromatic-C	3.4 - 3.6	3.6 - 3.8

^a Distance values are given as the lower and upper 90% percentiles of the corresponding histogram peak extracted from CSD searches. Interactions are formed with the atoms highlighted in red. In the case of aryl carbon atoms, the closest distances observed were chosen.

chains. Often, the C–S–C fragment is positioned in a coplanar fashion above the purine ring at van der Waals distance (~4.0 Å). This arrangement is exemplified by the complex of catechol-*O*-methyltransferase with its cofactor *S*-adenosylmethionine. The cofactor is sandwiched between Met 91 and His 142 (Figure 20). The distance between the sulfur atom and the closest ring atom is 3.6 Å. It has not been studied in detail whether this type of arrangement is predefined by the (often highly conserved) adenine binding pockets or whether it is due to the electronic nature of the adenine ring system. There is a second common geometric arrangement between adenine and methionine side chains in which the terminal methyl group forms the interaction as found in the ab initio model studies of dimethyl sulfide and benzene.²¹⁶ This geometry is also observed with other nucleobases, for example, in the complex between herpes simplex virus type 1 thymidine kinase and thymidine,²¹⁹ and it is confirmed as the preferred interaction geometry between phenyl rings and sulfur-bound methyl groups in the CSD (Figure S-8).

Summary of Typical Interaction Distances. It is our experience that successful interactive structure-based design as well as a meaningful analysis of experimental or calculated structures requires an intimate knowledge of the typical interaction geometries, in particular of the typical distances involved. We therefore conclude by listing typical interaction distance ranges in a separate table for reference purposes (Table 2). It lists distances for specific interactions discussed in the previous paragraphs, plus distance ranges of several further frequently occurring interactions. For interactions involving aromatic rings, we avoid distances to centroids and list atom–atom distances instead because these can be readily measured with most molecular modeling software packages.

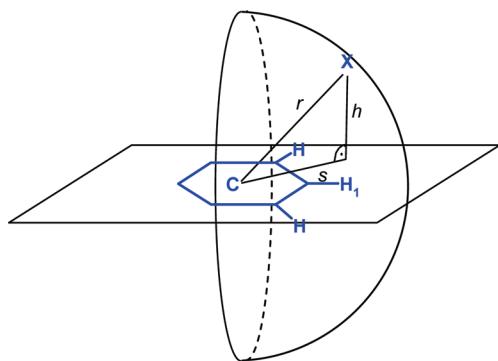

Figure 21. Query setup used for searching interactions between query atoms X and phenyl rings.

All distance ranges were derived by the same method (see Materials and Methods) from CSD data.

Conclusions

We have shown how an understanding of typical noncovalent protein–ligand interactions can arise from the synergistic use of crystal structure database searching, structures, and association properties of biomolecular and synthetic receptor–ligand systems and various computational models. Awareness of geometric preferences of a specific interaction enables its recognition and application in different contexts. Although a clear decomposition of the energetic contributions of individual interactions is, strictly speaking, impossible, approximate relative propensities can be derived. Keeping in mind the big picture, i.e., the likelihood of alternative interactions any particular group can undergo, helps to avoid the mistake of overemphasizing any particular interaction. In this sense, there is still a lot to be learned from crystal structure databases. The results of such studies should become textbook knowledge but could also very well serve as a basis for improved knowledge-based force fields on the basis of functional groups rather than pairwise atom contacts. Structure-based design can certainly benefit from neighboring disciplines, in particular the analysis of supramolecular synthons in crystal engineering and the inverse design processes applied in protein engineering, both of which may foster an increased understanding of larger recurring patterns beyond the concept of functional group interactions.

It is striking that the multitude of different interaction types reviewed here has not yet become part of crystal structure visualization and molecular design programs. Visualization often does not go beyond the concepts of hydrogen bonds and van der Waals contacts. We have implemented these non-classical types of interactions in our version of the macromolecular crystal structure database and visualization system, complemented by a flagging of unfavorable interactions such as unsatisfied hydrogen bond donors and acceptors in a lipophilic environment. Most of these options are now available in the form of PyMol scripts as part of Proasis2.²²⁰ Already such simple enhancements have led to a better understanding of protein–ligand interactions at play and were well received by medicinal chemists. In the short term, we see possibilities for further improvements in a better visual representation of poorly solvated binding pockets, which offer potentially large affinity gains. Local dipolar interactions have been touched upon in this article. Beyond that, helix dipoles can be very strong but, to our knowledge, have not been proactively used in the design process. Such secondary

structure elements can, for instance, be visualized in Relibase+.⁴⁷

The increased availability of structural information has led to a great amount of detailed knowledge, but it has also overly focused our attention on “visible interactions”. We need to become more aware of the fact that many effects not explicitly present in a receptor–ligand complex structure (solvation/desolvation effects, changes in mobility, cooperativity) play a large and sometimes dominant role. More holistic conceptual models such as the one proposed by Hunter⁸⁷ could increase the awareness of solvent effects; similar concepts for entropy might be hard to develop. An increased appreciation of entropic aspects can perhaps only grow on the basis of detailed investigations of individual model systems and accurate thermodynamic data. Studies that carefully probe the energetic contributions of individual subpockets or ligand components, such as the decomposition of known ligands into fragments, can provide a significant amount of insight and should become routine practice in medicinal chemistry.

Finally, as the level of confidence in structure-based design has increased, it is important to emphasize that any modeled binding mode remains a model until it is experimentally validated. Sadly, it has become common practice today to mingle models and reality. We close with a call for a more careful assessment of modeled structures. No binding modes from docking or molecular dynamics calculations should go unchallenged. The knowledge base for such scrutiny is large and is waiting for its application.

Materials and Methods

All statistical data on small molecule crystal structures described in this article were derived from searches in the CSD, version 5.30 (November 2008), with the ConQuest 1.11 program.²²¹ Unless noted otherwise, the following general search flags were set: R factor of ≤ 0.10 , “3D coordinates determined”, “not disordered”, “no ions”, “no errors”, “not polymeric”, and “only organic.” Protein–ligand interactions were analyzed by extracting binding sites in SD format²²² from Proasis2,²²⁰ a curated version of the PDB, and generating a separate database in CSD format with the program PreQuest.²²³ Binding sites were extracted around all HET entries, except metals and commonly found small ions, in the PDB as of December 8, 2008. Those with less than 5 or more than 100 ligand atoms were removed, excluding in particular large peptidic ligands. Multiple occurrences of the same ligand in one PDB structure were counted as separate entries. This database contains a total of 77 378 binding sites derived from 25 096 PDB entries. Queries were run in identical manner in the CSD and the PDB ligand database with one exception: For CSD searches, explicit hydrogen definitions were used, whereas the absence of hydrogen atoms in the PDB ligands required the use of implicit hydrogen counts on carbon.

Where preferred interaction distances are quoted in the text, they were derived in the following manner: Distance histograms were generated from counts divided by $4\pi r^2$, where r is the interaction distance, in order to account for the increasing volume available at larger distances. Histograms were plotted in 0.05 Å bins. The peaks in the distance histograms were visually located and characterized by their median and the lower and upper 90% percentiles (i.e., the range containing 80% of the hits). These are the range values given in the text and in Table 2. Angle distributions were treated in a similar fashion. Angles between geometric objects (atoms, planes) were normalized by the “cone correction” ($1/\sin(\text{angle})$).⁷⁹

To derive frequencies of occurrence of noncovalent interactions, CSD entries containing the interacting fragments exactly once were compiled. The frequency of occurrence is defined by

the fraction of entries that form the interaction within the geometric limits defined earlier.

Maps for interactions between functional groups and phenyl rings were created by measuring, for a query atom X, the distance above the phenyl ring plane h and the distance from the centroid to the query atom r (Figure 21). From these parameters, the in-plane distance between X and the centroid was calculated (centroid shift s). A limit of 7 Å was used for the centroid–X distance. To avoid spurious mapping of interactions “behind” the phenyl ring, queries were limited to a half sphere by limiting the angle C–H1–X to $\leq 90^\circ$. Plots of h vs s effectively project the space of this half sphere to two dimensions. Radial distribution plots were generated by counting hits in $0.1 \text{ \AA} \times 0.1 \text{ \AA}$ distance bins (h vs s) and scaled by $1/(2\pi r^2)$, where r is the distance between the centroid and the query atom X. In addition, all bins were scaled by the total number of counts.

All depictions of chemical structures in this article have been generated with PyMOL.²²⁴

Acknowledgment. We thank Julian Fuchs for support in compiling interaction statistics and Johannes Hermann, François Diederich, and Klaus Müller for many valuable discussions. We also thank two anonymous referees for many constructively critical comments and additional references.

Biographies

Caterina Bissantz earned her Pharm.D. (1998) from University of Freiburg, Germany, her M.Sc. (1999) from Purdue University, West Lafayette, IN, under the supervision of Dr. Don Bergstrom in the field of synthetic medicinal chemistry, and her Ph.D. (2002) from ETH Zurich, Switzerland, under the supervision of Prof. Gerd Folkers and Dr. Didier Rognan in the field of virtual screening and GPCR modeling. In 2002, she joined Roche, where she is a member of the Molecular Design Group. Her special areas of interest are structure-based and GPCR drug design. She has coauthored more than 40 papers and patents.

Bernd Kuhn received his M.S. in Chemistry (1994) from the University of Karlsruhe, Germany, and Ph.D. (1998) from the Swiss Federal Institute of Technology, Lausanne, Switzerland, under the supervision of Prof. Tom Rizzo. Following postdoctoral studies as a DAAD fellow in macromolecular simulations with Prof. Peter Kollman at the University of California, San Francisco, he joined the start-up company Prospect Genomics in 2000. In 2001 he moved to F. Hoffmann-La Roche, Basel, Switzerland, where he is a member of the Molecular Design group with a focus on structure-based computational methods and their application to drug design projects. His scientific contributions include more than 90 papers and patents.

Martin Stahl received his Ph.D. in Theoretical Chemistry from the University of Marburg, Germany, under the supervision of Prof. G. Frenking. He joined Roche in 1997 and initially worked on structure-based design projects at the Basel and Palo Alto sites. In 2001, he was appointed head of molecular design in Basel. Since 2005, he has been a section head in medicinal chemistry. A member of the global chemistry leadership team, he is responsible for the Roche-wide coordination of molecular design and cheminformatics work. He has helped to develop and apply multiple novel methods in computational chemistry and is a fervent advocate of joint interactive design sessions between chemists and molecular designers. Martin has coauthored over 60 scientific articles and is an Advisory Board Member of *Journal of Medicinal Chemistry*.
